Thrombomodulin mutant mice with a strongly reduced capacity to generate activated protein C have an unaltered pulmonary immune response to respiratory pathogens and lipopolysaccharide

Anita W. Rijneveld, Sebastiaan Weijer, Sandrine Florquin, Charles T. Esmon, Joost C. M. Meijers, Peter Speelman, Pieter H. Reitsma, Hugo Ten Cate, and Tom van der Poll

The thrombomodulin–protein C–protein S (TM-PC-PS) pathway exerts anticoagulant and anti-inflammatory effects. We investigated the role of TM in the pulmonary immune response in vivo by the use of mice with a mutation in the TM gene (TMpro/pro) that was earlier found to result in a minimal capacity for activated PC (APC) generation in the circulation. We here demonstrate that TMpro/pro mice also display a strongly reduced capacity to produce APC in the alveolar compartment upon intrapulmonary delivery of PC and thrombin. We monitored procoagulant and inflammatory changes in the lung during Gram-positive \textit{(Streptococcus pneumoniae)} and Gram-negative \textit{(Klebsiella pneumoniae)} pneumonia and after local administration of lipopolysaccharide (LPS). Bacterial pneumonia was associated with fibrinogen deposition in the lung that colocalized with inflammatory infiltrates. LPS also induced a rise in thrombin-antithrombin complexes in bronchoalveolar lavage fluid. These pulmonary procoagulant responses were unaltered in TMpro/pro mice, except for enhanced fibrinogen deposition during pneumococcal pneumonia. In addition, TMpro/pro mice displayed unchanged antibacterial defense, neutrophil recruitment, and cytokine/chemokine levels. These data suggest that the capacity of TM to generate APC does not play a role of importance in the pulmonary response to respiratory pathogens or LPS. (Blood. 2004;103:1702-1709)

Introduction

Thrombomodulin (TM) is a membrane glycoprotein that forms a high-affinity complex with thrombin. The thrombin-TM complex plays a central role in the regulation of coagulation by converting protein C (PC) to its activated form (APC), a process that is facilitated by the endothelial protein C receptor (EPCR).\textsuperscript{1} APC has antithrombotic properties, together with its cofactor protein S (PS), by inactivating factor V a and VIIIa, and has profibrinolytic properties by forming complexes with plasminogen activator inhibitor type 1 (PAI-1), the main inhibitor of plasminogen activation.\textsuperscript{1,2} In addition to these anticoagulant properties, APC also attenuates several inflammatory responses. The anti-inflammatory activities of APC are mainly due to inhibition of leukocyte activation, tumor necrosis factor (TNF) production, and E-selectin–mediated cell adhesion to endothelial cells.\textsuperscript{3,7} Evidence indicates that the expression and function of TM and EPCR are diminished in sepsis in humans; this together with decreased PC levels may cause reduced generation of APC.\textsuperscript{8,9} Such a reduction in endogenous APC activity had dramatic consequences in experimental sepsis in baboons. Indeed, either infusion of anti-APC or anti-EPCR antibody and the administration of C4b binding protein, reducing the bioavailability of PS, exacerbated the response to an intravenous \textit{Escherichia coli} challenge, converting a sublethal model into a severe shock response associated with lethality.\textsuperscript{10-12} In accordance, administration of exogenous APC prevented tissue injury and death induced by infusion of a lethal dose of \textit{E. coli}.\textsuperscript{10} Moreover, recently it has been reported that treatment with APC reduced mortality in patients with severe sepsis.\textsuperscript{13}

Also in the pulmonary compartment, APC exerts strong anti-inflammatory effects. Intravenous infusion of APC protected endotoxemic rats against lung injury by inhibition of leukocyte activation\textsuperscript{14} and intratracheal administration of APC attenuated bleomycin-induced lung inflammation in mice.\textsuperscript{15} Interestingly, TM expression varies in different organs. In lungs TM mRNA and TM antigen are both expressed at high levels in comparison with other organs.\textsuperscript{16-21} Together these findings led us to postulate a possible relationship between TM and pulmonary inflammation in vivo. In the present study, we sought to examine this relationship by making use of mice with a mutation in the TM gene that results in a minimal capacity for APC generation.\textsuperscript{22} We compared procoagulant and inflammatory responses in the lungs of these mice with responses of wild-type (Wt) mice after pulmonary instillation of \textit{Streptococcus pneumoniae}, the predominant cause of Gram-positive pneumonia; \textit{Klebsiella pneumoniae}, a frequently encountered Gram-negative respiratory pathogen; or lipopolysaccharide (LPS) to induce a sterile inflammation.

Materials and methods

Animals

Mice with a single amino acid substitution (Glu404Pro) in the gene for TM, kindly provided by Dr R. D. Rosenberg (Massachusetts Institute of Technology, Cambridge), were generated on a C57BL/6 (and B6D2F1) background, as previously described. Homozygous mutant TMpro/pro mice exhibit a decrease of approximately 1000-fold with respect to PC activation and approximately 100-fold with respect to binding of thrombin at physiological levels of the enzyme. Yet in contrast to TM–/– mice, which die in the embryonic stage, TMpro/pro mice develop to term and possess normal reproductive performance. All mice were on a C57BL/6 background. The wild types of the TMpro/pro mice were derived from original litters. All experiments were approved by the Committee on Use and Care of Animals of the Academic Medical Center, Amsterdam, The Netherlands.

APC measurement in the alveolar compartment

Mice were anesthetized by inhalation of isoflurane (Upjohn, Ede, The Netherlands). The trachea was exposed through a midline incision. A total of 16 wild-type and 16 TMpro/pro mice received one of the following treatments (dissolved in 50 µL sterile normal saline) via direct intratracheal injection (4 mice per strain for each treatment): (1) saline only (control), (2) thrombin (1 µg), (3) human protein C (50 µg), or (4) thrombin and human protein C. Directly thereafter the wound was sutured. After 30 minutes, mice were anesthetized again using an intraperitoneal injection with Hypnorm (Janssen Pharmaceutica, Beerse, Belgium) and midazolam (Roche, Mijdrecht, The Netherlands). The trachea was exposed and cannulated with a sterile 22-gauge Abbott Cath-T catheter (Abbott, Sligo, Ireland). A bronchoalveolar lavage (BAL) was performed by instilling 2 aliquots of 0.5 mL sterile saline containing 10 mM citrate and 20 mM benzamidine (pH 7.4) to reversibly inhibit APC. Thrombin, protein C, and activated protein C (APC) were generous gifts from Dr W. Kisiel (University of New Mexico, Albuquerque). APC levels were determined in BAL fluid (BALF) as described by Liaw et al. After recalcification of the BAL samples, APC was captured by a specific calcium-dependent monoclonal antibody (HAP1C1555), generously provided by C.T.E. The activity of the bound APC could be determined toward the chromogenic substrate S2366 (Chromogenix, Mölndal, Sweden) after removal of benzamidine by a washing step. A dilution curve of APC in BALF was taken as a standard.

Induction of lung inflammation

Pneumococcal pneumonia was induced as described previously. S. pneumoniae (ATCC 6303; American Type Culture Collection, Rockville, MD) were suspended in sterile isotonic saline at approximately 0.5 × 10^7 to 1 × 10^8 colony-forming units (CFUs) per milliliter, as determined by plating serial 10-fold dilutions on sheep-blood agar plates. For induction of Gram-negative pneumonia, K pneumoniae serotype 2 (ATCC 43816) was used. Bacteria were diluted in sterile isotonic saline at approximately 3 × 10^8 CFUs per milliliter. LPS (10 µg; from E coli 0111:B4) was obtained from Sigma (St Louis, MO) and dissolved in 50 µL sterile saline. Mice were lightly anesthetized by inhalation of isoflurane (Abbott, Queensborough, United Kingdom), and 50 µL bacterial suspension or LPS was inoculated intranasally. Control mice were instilled intranasally with 50 µL sterile saline. The time points at which mice were killed were chosen because they were found to be representative for a particular model (ie, S pneumoniae pneumonia, 48 hours; K pneumoniae pneumonia, 24 hours; LPS inflammation, 6 hours;25,26 data not shown).

Preparation of lung homogenates

At 6, 24, or 48 hours after inoculation, mice were anesthetized by intraperitoneal injection with Hypnorm (Janssen Pharmaceutica) and midazolam (Roche), and blood was collected from the inferior caval vein. Whole lungs were harvested and homogenized at 4°C in 5 volumes of sterile isotonic saline with a tissue homogenizer (Biospect Products, Bartlesville, OK) that was carefully cleaned and disinfected with 70% ethanol after each homogenization. Serial 10-fold dilutions in sterile saline were made from these homogenates (and blood), and 50 µL volumes were plated onto sheep-blood agar plates and incubated at 37°C and 5% CO2. CFUs were counted after 16 hours. For cytokine measurements, lung homogenates were lysed in lysis buffer (300 mM NaCl, 15 mM Tris [tris(hydroxymethyl)aminomethane], 2 mM MgCl2, 2 mM Triton X-100), pepstatin A, leupeptin, and aprotinin (20 ng/mL) (pH 7.4) and spun at 1500g at 4°C for 15 minutes; the supernatant was frozen at −20°C for cytokine measurement.

Cell counts in BALF

BAL was performed as described above; 0.9 to 1 mL lavage fluid was retrieved per mouse, and total cell numbers were counted from each sample in a hemacytometer. BALF differential cell counts were determined on cytospin preparations stained with modified Giemsa stain (Diff-Quick; Baxter, McGraw Park, IL).

Histologic examination

After 24-hour fixation of lungs in 10% formalin and embedding in paraffin, 4-µm-thick sections were stained with hematoxylin and eosin. All slides were coded and scored by a pathologist without knowledge of the genotype of mice and treatment. For fibrin(ogen) staining, slides were deparaffinized and endogenous peroxidase activity was quenched with a solution of methanol/0.03% H2O2 (Merck, Darmstadt, Germany). After digestion with a solution of pepsin 0.25% (Sigma) in 0.01M HCl, the sections were incubated in 10% normal goat serum (Dako, Glostrup, Denmark) and then exposed to biotin-labeled goat antimouse fibrin(ogen) antibody (Ixe; Accurate Chemical & Scientific, Westbury, NY). After washes, slides were incubated in a streptavidin-ABC solution (Dako) and developed using 1% H2O2 and 3,3′-diaminobenzidine-tetra-hydrochloride (Sigma) in Tris-HCl. The sections were mounted in glycerin gelatin without counterstaining and analyzed.

For TM staining, endogenous peroxidase activity was quenched by a solution of 1.5% H2O2 (Merck) in phosphate-buffered saline (PBS) and nonspecific binding blocked by incubation with Teng-T, pH 8.0. Slides were then incubated with a rat antimouse monoclonal antibody (mAb) (kindly provided by Dr S. J. Kennel, Oak Ridge National Laboratory, Oak Ridge, TN). Slides were then exposed to a biotinylated rabbit antirat polyclonal AB (Dako), further incubated in a streptavidin-ABC solution (Dako), and developed using 1% H2O2 and 3,3′-diaminobenzidine-tetra-hydrochloride (Sigma) in Tris-HCl. The sections were mounted in glycerin gelatin after a slight methyl green counterstaining and analyzed.

Assays

Cytokine and chemokine levels were measured by using commercially available enzyme-linked immunosorbent assays (ELISAs), in accordance with the manufacturers’ recommendations: TNF, interleukin-6 (IL-6) (Pharmining, San Diego, CA), interleukin–1β (IL-1β), macrophage inflammatory protein-2 (MIP-2), and KC (R&D Systems, Abingdon, United Kingdom). Detection limits were 150 pg/mL (TNF and IL-1β), 75 pg/mL (IL-6), 47 pg/mL (MIP-2), and 12 pg/mL (KC). Myeloperoxidase (MPO) activity was measured as described previously. Briefly, lungs were homogenized in 10% (wt/vol) homogenization buffer (50 mM phosphate buffer [pH 6.0]) containing 0.5% hexadecyltrimethylammonium bromide). After centrifugation (4500g for 20 minutes at 4°C), 0.1 mL supernatant was added to 0.55 mL of 0.1 M phosphate buffer (pH 6.0) containing 1.25 mg/mL o-dianisidine and 0.05% hydrogen peroxide. After 5 minutes, the change in absorbance at 460 nm was measured with a spectrophotometer. Purified MPO was used as a standard. Results were expressed as units of MPO activity per gram of tissue. Thrombin-antithrombin complexes (TATc’s) were measured in heparin-anticoagulated plasma and in bronchoalveolar lavage fluid with an ELISA-based method. Briefly, rabbits were immunized with mouse thrombin or rat antithrombin. Antithrombin antibodies were measured...
used as capture antibody, digoxigenin-conjugated anti-antithrombin antibodies were used as detection antibodies, horseradish peroxidase–labeled sheep antidigoxigenin (anti-DIG) F(ab')2 fragments (Boehringer Mannheim, Mannheim, Germany) were used as staining enzyme, and o-phenylene-diamine dihydrochloride (OPD, Sigma) was used as substrate. Dilutions of mouse serum (Sigma) were used for the standard curve, yielding a lower detection limit of 0.3 ng/mL.28

Statistical analysis

Data are expressed as means ± SEM unless indicated otherwise. Comparisons between groups were conducted using the Mann-Whitney U test. Survival curves were compared by log-rank test. A P value of less than .05 was considered to represent a statistically significant difference.

Results

Protein C activation in the alveolar space

To evaluate whether PC activation takes place in the alveolar space and whether TM regulates this activation, we administered thrombin, protein C, or both intratracheally in Wt and TMpro/pro mice and measured APC in BALF 30 minutes later (Table 1). Administration of saline or thrombin alone did not result in APC generation in Wt or TMpro/pro mice. Administration of PC only resulted in minimal APC generation in TMpro/pro mice. A BAL was performed after 30 minutes, and human APC (ng/mL) was measured herein. Data are means ± SE of 4 mice per group for each treatment.

Table 1. Reduced protein C activation in BALF of TMpro/pro mice

Thrombin and/or protein C (PC) were administered intratracheally in Wt and TMpro/pro mice. A BAL was performed after 30 minutes, and human APC (ng/mL) was measured herein. Data are means ± SE of 4 mice per group for each treatment. *P < .05 versus Wt mice.

Activation occurs in the alveolar space and at least in part is regulated by TM.

Gram-positive pneumonia

We used S pneumoniae as a Gram-positive respiratory pathogen. This bacterium is the most frequently encountered pathogen in community-acquired pneumonia29 and is able to induce a procoagulant state on endothelial cells in vitro.30,31 To determine whether pneumococcal pneumonia activates coagulation in the systemic compartment, TATc’s were measured in plasma. Plasma concentrations of TATc’s did not differ from uninfected control mice at 48 hours after administration of S pneumoniae (data not shown).

Furthermore, no difference was found between Wt and TMpro/pro mice after induction of pneumonia. We next determined whether coagulation was activated at a local level in the alveolar compartment. However, neither group had detectable levels of TATc’s in BALF 48 hours after induction of pneumococcal pneumonia. Besides TATc measurements to evaluate coagulation activation, we also examined lung tissue deposition of fibrinogen. Antifibrinogen immunostaining showed fibrinogen deposition that colocalized with the inflammatory infiltrates. No fibrin clots were seen in pulmonary vessels. TMpro mice showed more extensive fibrinogen deposition compared with Wt mice and a strong staining of the pleura (Figure 1C-D).

Having established that TM is important for the inhibition of coagulation at tissue level during pneumococcal pneumonia, we next determined the role of APC generation in host defense 48 hours after inoculation. The numbers of CFUs recovered from the lungs (Figure 2A) and blood (data not shown) were similar in TMpro mice and Wt mice. Because APC has been shown to influence pulmonary cell recruitment after intravenously administered LPS,14 we assessed neutrophil influx into the alveolar compartment. No difference was seen in the number of neutrophils in BALF between the 2 groups at 48 hours after inoculation with S pneumoniae (Figure 3A). In addition, MPO was measured in lung homogenates, as a neutrophil marker enzyme, and found to be similar in Wt and TMpro mice (Figure 3D). Histologically, the inflammation was comparable in both groups, although more perivascular edema was present in TMpro mice (Figure 1A-B). During infection local...
cytokine responses are necessary to mount an adequate inflammatory reaction.32 We measured TNF, IL-1β, IL-6, KC, and MIP-2 in lung homogenates and found no difference between Wt and TMpro/pro mice (data not shown). Finally, mortality did not differ between Wt and TMpro/pro mice during a 10-day follow-up (11 of 11 versus 9 of 11 mice, respectively; nonsignificant).

**Gram-negative pneumonia**

Next, we evaluated whether TM is involved in the pulmonary response to *Klebsiella pneumoniae*, a common pathogen in Gram-negative bacterial pneumonia. First we examined whether this Gram-negative bacterium was able to induce coagulation either systemically or locally. TATc’s in plasma or BALF did not differ in infected Wt and TMpro/pro mice compared with uninfected control mice (data not shown). At tissue level activation of coagulation could be detected in mice with Gram-negative pneumonia. Fibrinogen was mainly observed in the pulmonary interstitium and around vessels in both mouse strains to the same extent (Figure 4C-D).

With respect to host defense, no difference in the number of CFUs was found in lungs and blood of TMpro/pro and Wt mice 24 hours after inoculation (Figure 2B). To determine whether the inflammatory response to *K pneumoniae* was influenced by TM, we assessed the number of neutrophils recruited to the alveoli. No difference in neutrophil counts was found in BALF of Wt and TMpro/pro mice 24 hours after inoculation (Figure 3B). Also, lung MPO activity did not differ between the 2 groups (Figure 3E). Histopathology showed no difference in composition and distribution of the inflammatory infiltrates (Figure 4A-B). Cytokine and chemokine levels in lung homogenates were similar in both groups (data not shown).

**LPS-induced lung inflammation**

LPS is a major pathogenetic factor in Gram-negative sepsis. Systemic LPS administration caused hemodynamic and inflammatory changes but also lung damage. Recombinant soluble TM and APC were able to prevent these effects.14,33-35 To investigate whether TM has a similar role after local exposure to LPS in vivo, we inoculated Wt and TMpro/pro mice intranasally with LPS. No significant increase in plasma TATc’s was seen in Wt mice and TMpro/pro mice compared with control mice (data not shown). However, at the local level, there was a brisk increase of TATc’s in BALF of Wt and TMpro/pro mice compared with control mice (Figure 5). No difference in BALF TATc levels was found between TMpro/pro and Wt mice. Fibrinogen deposition was mainly seen around large vessels and was slightly more pronounced in TMpro/pro mice. Thrombi were not observed (Figure 6C-D).

We evaluated the inflammatory response in the lung by determining the influx of neutrophils. No difference could be found in the recruitment of neutrophils into the BALF of Wt and TMpro/pro mice (Figure 3C). MPO content in lung homogenates did not significantly differ between the 2 groups (Figure 3D). On histopathological examination the lungs showed endothelialitis, perivascular inflammation, and interstitial inflammation to the same extent in Wt and TMpro/pro mice. Thrombi were not observed (Figure 6A-B). Cytokine and chemokine levels in lung homogenates were similar in both groups (data not shown).

**TM expression**

In patients with severe sepsis, TM expression is down-regulated in the dermal microvasculature.8 To evaluate the possibility that this also occurs in the lung during pulmonary infection and inflammation, we compared the expression of TM in normal and inflamed lungs using anti-TM immunostaining in Wt and TMpro/pro mice (Figure 7). Normal lungs showed a delicate network of TM expression along the interalveolar capillaries (Figure 7A-B). Decreased TM staining was observed after LPS administration (Figure 7C-D). After *K pneumoniae* and *S pneumoniae* infection, TM staining was strongly diminished in the inflamed areas (Figure 7E-H). The pattern of immunoreactivity for TM was similar in TMpro/pro mice (Figure 7B,D,F,H).
Discussion

APC, both endogenously produced and exogenously administered, plays an important role in the regulation of coagulation and inflammation. The production of endogenous APC requires an interaction between thrombin and TM. The function of TM in disease cannot be studied using TM gene–deficient mice, because these die in the embryonic stage. Therefore, in the present study we made use of mice with a point mutation in the TM gene, resulting in viable mice with a severely reduced capacity to generate APC. We were interested in TM function during lung inflammation, because TM is preferentially expressed in the pulmonary compartment and APC has been reported to exert potent anti-inflammatory effects in lungs. Moreover, the beneficial effect of recombinant human APC in a recent clinical sepsis trial was obtained in a study population that predominantly consisted of patients with pneumonia. We here report that experimental Gram-positive (S pneumoniae) and Gram-negative (K pneumoniae) pneumonia is associated with fibrinogen deposition in lung tissue, which were modestly enhanced in TMpro/pro mice in pneumococcal pneumonia only. Local LPS administration resulted in generation of TATc in the alveolar compartment, which was not altered by functional TM deficiency. Furthermore, we showed that TM is neither important for antibacterial defense in the lung nor for lung inflammation in response to bacteria or LPS.

Previous studies have established that TMpro/pro mice exhibit a 100-fold reduction with respect to binding of thrombin and a 1000-fold reduction with respect to PC activation in the circulation when compared with Wt mice; the incapacity of TMpro/pro mice to activate PC was demonstrated using an indirect approach (ie, mice were intravenously injected with human PC, after which human APC levels were determined using an immunocapture assay). In the present investigation we wished to exclude the possibility that even in Wt mice TM is not expressed to a biologically significant extent in the alveolar space; if this were the case, TM would not be expected to play a role in the regulation of coagulation in this compartment. We therefore intratracheally administered human PC with or without thrombin and measured APC in BALF 30 minutes later. PC alone induced little if any APC generation, suggesting that thrombin is not present in the normal alveolar space. Administration of PC with thrombin, however, resulted in a strong rise in APC levels in BALF of Wt mice. TMpro/pro mice, however, displayed a strongly reduced capacity to generate APC in their alveolar space (a 25-fold reduction when compared with Wt mice). Although these data indicate that indeed APC can be generated in the alveolar space and that TM plays a major role herein, it should be noted that the extent of reduction in APC generation in TMpro/pro mice is less than that previously reported for APC generation capacity in the circulation. It therefore remains to be established whether other factors can contribute to APC generation in the alveolar compartment.

In all 3 models studied, TM expression was reduced in areas of lung inflammation in both TMpro/pre and Wt mice. This finding is in line with a recent investigation showing diminished TM expression in the dermal microvasculature of children with severe meningococemia and raises the possibility that the almost complete absence of functional TM in TMpro/pre mice does not have a major effect on the pulmonary host response because already in normal Wt mice TM expression and APC generation are reduced to a significant extent.

In Gram-negative sepsis the importance of the coagulation system has been well documented. Treatment with DEGR-FXa (a selective inhibitor of thrombin generation) or heparin prevented the coagulopathy related to sepsis but did not increase survival. In contrast, treatment with recombinant human TM (rh-TM) or APC decreased tissue injury as well as mortality in animal models of disseminated intravascular coagulation (DIC). Moreover,
recombinant APC significantly reduced mortality in septic patients, which was associated with reduced circulating d-dimer and IL-6 levels.\(^{11}\) Interventions inhibiting the endogenous TM-PC-PS pathway strongly enhanced mortality after intravenous infusion of E coli.\(^{10-12}\) In accordance, TMpro/pro mice displayed a significantly reduced survival compared with Wt mice after intraperitoneal administration of LPS.\(^{79}\) Thus, TM does play a very important role with respect to hemostasis and inflammatory responses during sepsis and endotoxemia, both providing severe systemic challenges.

Interestingly, while our studies were in progress Conway et al reported several anti-inflammatory properties of endogenous TM that were unrelated to its anticoagulant properties.\(^{40}\) These authors generated transgenic mice that lack the NH\(_2\)-terminal (lectin) domain of TM; these TMLeD/LeD mice were shown to have normal TM antigen levels and to retain the capacity to generate APC. TMLeD/LeD mice were found to have a reduced survival after intraperitoneal injection of LPS together with elevated circulating cytokine levels. In an experiment that resembled one of the studies described in the present paper, TMLeD/LeD mice were exposed to LPS via a nebulizer and neutrophil influx in BALF was measured 3 hours later. At this time point absolute neutrophil counts were 2-fold higher in TMLeD/LeD mice. In addition, TMLeD/LeD mice not challenged with LPS were found to have relatively more neutrophils in their lung parenchyma than Wt mice. In a series of in vitro experiments, these authors further showed that the lectin domain of TM interferes with neutrophil adhesion to endothelial cells by intracellular adhesion molecule-1-dependent and –independent pathways through the suppression of extracellular signal-regulated kinase (ERK)\(_{1/2}\) activation.\(^{40}\) These elegant studies clearly indicate that TM, and in particular its lectin domain, has anti-inflammatory properties that can be dissected from the anticoagulant properties of TM. In this respect it is important to realize that the TMpro/pro mice used here have an intact TM lectin domain. It is therefore possible that intact TM does play a role in the pulmonary infection and inflammation models described here. Nonetheless, our studies clearly reveal that the capacity of TM to interact with thrombin to generate APC (ie, the anticoagulant properties of TM) are unlikely to be involved in the regulation of lung inflammatory responses.

Notably, several studies have revealed that exogenously administered (recombinant human) TM and APC are both able to attenuate lung injury related to DIC by inhibiting leukocyte activation\(^{14,33,35,41}\) and that intratracheal administration of APC exerts anti-inflammatory effects in bleomycin-induced lung fibrosis.\(^{53}\) Furthermore, leukocyte activation was also inhibited by APC after renal and spinal cord injury in rats.\(^{42-44}\) On the other hand, APC did not influence pulmonary leukocyte accumulation in an intestinal ischemia/reperfusion model or in the skin in immune complex–mediated skin inflammation.\(^{45}\) This demonstrates that the effects of APC on leukocyte activation and recruitment differ between models.

TMpro/pro mice display a prothrombotic state and an increased susceptibility to thrombosis.\(^{22,39}\) During pneumonia in humans the coagulation system has been shown to become activated in the alveolar space.\(^{46-48}\) The results of the present study suggest that coagulation is activated after exposure of the lung to S pneumoniae, K pneumoniae, and LPS, as indicated by fibrinogen depositions in the parenchyma of the lung. However, only after LPS instillation was there activation of the coagulation system in the alveolar space as well. Accordingly, adult respiratory distress syndrome (ARDS) patients showed more profound alterations in the alveolar hemostatic balance than patients with bronchopneumonia.\(^{46}\) In addition, it is possible that in the LPS challenge model the brisk and strong proinflammatory stimulus that remains within the alveolar space is sufficient to cause a significant rise in BALF TATc levels, whereas this is not the case in the lung infection models in which the bacterial load gradually increases primarily in lung tissue. We found a remarkable variation in fibrinogen deposition in lung tissue in the 3 different models used. These fibrinogen deposits colocalized with the inflammatory infiltrates. When TMpro/pro mice were exposed to S pneumoniae, K pneumoniae, and LPS, only during pneumococcal pneumonia, enhanced fibrin deposition was observed in the lung and in the pleura in TMpro/pro mice compared with Wt mice. This suggests that only during pneumococcal pneumonia is TM necessary for adequate anticoagulant activity. Other natural inhibitory pathways, such as tissue factor pathway inhibitor (TFPI), antithrombin, nitric oxide (NO) synthetase, and prostacyclin synthetase, may counteract this defect in BALF TATc levels, whereas this is not the case in the lung infection models in which the bacterial load gradually increases primarily in lung tissue.

TM is a widely expressed receptor that can mediate both anticoagulant and anti-inflammatory effects. Recent evidence indicates that these 2 properties at least in part can be separated—that is, the NH\(_2\)-terminal lectin domain of TM displays several
anti-inflammatory properties that are unrelated to the anticoagulant properties of TM. Using TMpro/pro mice, which have a strongly reduced capacity to interact with thrombin and to generate APC in the circulation and in the alveolar space (the present paper), we provide evidence that the anticoagulant properties of TM do not importantly contribute to the host pulmonary response to locally administered bacteria or LPS, at least not in the experimental settings used here. Further investigations are warranted to determine the role of the lectin domain of TM in the host response to bacterial pneumonia and LPS-induced lung inflammation.
