Mechanisms of hypergammaglobulinemia and impaired antigen-specific humoral immunity in HIV-1 infection

Angelo De Milito, Anna Nilsson, Kehmia Titanji, Rigmor Thorstensson, Elisabet Reizenstein, Mitsuo Narita, Sven Grutzmeier, Anders Sönnerborg, and Francesca Chiodi

Introduction

A profound impairment of immune functions occurs in individuals infected with human immunodeficiency virus type 1 (HIV-1). Both the cellular and the humoral arms of the immune system are unable to control the infection, which ultimately results in severe exhaustion of several lymphocyte functions and increased susceptibility to secondary and opportunistic infections. Major immunologic defects occur in the B-cell compartment. Polyclonal B-cell activation is demonstrated by hypergammaglobulinemia and spontaneous antibodies (Abs) production by cultured peripheral lymphocytes; additional signs of B-cell abnormality are the high antibodies (Abs) production by cultured peripheral lymphocytes demonstrated by hypergammaglobulinemia and spontaneous stimulation.9-11

In HIV-1 infection. A direct effect of virus replication or viral proteins on B-cell function has been shown and sustained by the observation that polyclonal B-cell activation is strongly reduced following effective antiretroviral treatment.13-15 HIV-driven unbalanced production of several cytokines like tumor necrosis factor α (TNF-α), interleukin 6 (IL-6), IL-10, and IL-15 has also been involved in B-cell dysfunctions.16-18 Defective T-cell help may account for B-cell unresponsiveness to T-cell–dependent antigens.19,20 The defect of B cells in HIV-1 infection appears, however, to be intrinsic since it begins early during infection preceding functional and quantitative defects in T-helper activity and cannot be restored by allogenic normal CD4+ T cells in vitro.21

The mechanisms inducing hypergammaglobulinemia in HIV-1 infection are only partially known. Activation driven by CD4+ T cells, monocytes, and natural killer (NK) cells through CD40-CD40 ligand (CD40L) interaction and an inappropriate cytokine supply may have a relevant role in inducing abnormal differentiation of B cells.17,22 In addition, HIV-1 itself may directly affect B-cell activation and dysfunction, inducing the appearance of a subset of CD21- B cells which have been proposed to contribute to increased antibody production.23,24 A recent work by Hunziker et al25 has suggested that naive B cells represent an important source of hypergammaglobulinemia and autoantibody production in chronic viral infections.

Because of the lack of protective humoral immunity, HIV-1–infected individuals receive vaccination against several pathogens. However, many studies have reported an impaired humoral immune response in most of the patients after vaccination.9-11,26,27

Immunologic memory represents an important mechanism of protection against reinfection and the basis for clinically successful vaccines.28,29 We have recently shown that memory B lymphocytes are significantly reduced during HIV-1 infection and are prone to undergo spontaneous apoptosis in vitro.6,30 The loss of memory B cells may be mediated by overexpression of CD70 on activated T lymphocytes,6,31 which may induce terminal differentiation to plasma cells and/or by lack of survival factors leading to apoptosis.30

In the present study, we investigated the phenotype and function of naive B cells isolated from HIV-1–infected persons and evaluated the status of antigen-specific humoral immunity in relation to hypergamma globulinemia and loss of memory B cells. The results of our study indicate that hyperactivated naive B cells may significantly contribute to hypergamma globulinemia and autoantibody production. Moreover, in the course of HIV-1 infection there is a selective damage to the memory B-cell population that translates into depressed serologic memory.

Patients, materials, and methods

Patients

This study included 72 HIV-1–infected subjects and 23 blood donors of similar age. The ethical committees of the Huddinge Hospital and the South Hospital (Stockholm) approved the study and all individuals gave informed consent to participate. Among the infected subjects, 54 were men and 18 were women. The median CD4+ T-cell count was 400 cells/µL (range, 40 cells/µL–1130 cells/µL). In the patients’ cohort, 13 subjects were treatment naive. 5 were treated with reverse transcriptase inhibitors, and 54 were undergoing highly active antiretroviral therapy (HAART), a combination therapy containing inhibitors of the viral protease and reverse transcriptase.

In the population analyzed in the present study, measures represent a naturally acquired infection and more than 95% of the healthy adult Swedish population carry protective antimouse antibodies level (Kari Johansen, personal written communication, September 2001). Regarding tetanus, 90% of the healthy male Swedish population between 20 and 50 years old is expected to have protective anti-tetanus toxoid (TT) Ab levels (> 0.01 IU/mL) because of the TT boost received during the military service, whereas about 60% of the female population carries protective anti-TT levels.32

Cell preparation and culture

Peripheral blood mononuclear cells (PBMCs) from HIV-1–infected and healthy subjects were purified from 30 mL to 40 mL of EDTA (ethylenediaminetetraacetic acid)–treated whole blood by centrifugation over a Ficoll–Hypaque density gradient. Plasma samples were collected and stored at −80°C.

PBMCs were cultured in RPMI 1640 supplemented with 10% fetal calf serum (FCS) and antibiotics. Supernatants for IgG secretion measurement were collected after 7 days when culture supernatants were collected and analyzed by IgG ELISA.33

Naive (CD19+CD27+) B lymphocytes were obtained from 8 patients and 4 donors by using a 2-step magnetic cell sorting procedure. PBMCs were incubated with CD19 multisort microbeads (Miltenyi Biotech, Bergisch Gladbach, Germany) and applied to an MS® column (Miltenyi Biotech). Positively sorted B cells were eluted from the column, treated with the release reagent to remove magnetic particles, and further applied to a new column to remove remaining magnetically labeled cells. The released B-cell fraction was further incubated with CD27 microbeads and applied to another column to obtain naive B cells from the CD27+ fraction. Fluorescence-activated cell-sorting (FACS) analysis by anti-CD27–phycoerythrin (PE) showed that more than 95% of the released naive B cells were CD27+. Naive B cells were cultured in RPMI 1640 medium at 0.5 × 106 cells/mL and cell culture supernatants were collected after 7 days and kept at −20°C for analysis of total IgG content.

Cell death of B lymphocytes

In a group of 26 patients and 8 controls, total B lymphocytes were purified by magnetic cell sorting using CD19 microbeads (Miltenyi Biotech). Purified B cells were cultured overnight in RPMI medium and quantification of cell death was performed by flow cytometry analysis. B cells were stained with anti-CD27–PE monoclonal Ab and annexin-V–fluorescein isothiocyanate (FITC; Pharmingen, San Diego, CA) in order to detect apoptosis of memory B lymphocytes.

Total IgG quantification

The amount of plasma IgG was measured by nephelometric analysis and the secretion of IgG in vitro was measured by sandwich IgG ELISA.33

Specific antibody measurement

Antibody titers against measles, TT, and HIV-1 were measured as follows. A standard in-house indirect quantitative enzyme immunoassay was used to determine measles Ab concentrations while the avidity testing was performed using the Enzygnost Measles virus IgG detection ELISA kit (Dade-Behring, Marburg, Germany) as previously described.34 The cut off for protective levels was set to more than 0.2 IU/mL35 and avidity (%) was calculated as the ratio of the absorbance values with and without urea treatment. Determination of anti–HIV-1 antibody titers was performed by using the Enzygnost HIV½ Plus ELISA (Dade-Behering) following the manufacturer’s instructions. Antibody levels to TT were evaluated by an accredited modified Delta test previously described.36

Determination of polyspecific self-reactive antibodies

The presence of polyspecific self-reactive antibodies (PSAs) has been described in HIV–1–infected subjects.37,38 Measurement of PSAs was performed as previously described.37 Buffy coat preparations from healthy donors were used to obtain target lymphocytes. The monocyte fraction was removed by plastic adherence incubating the PBMCs in RPMI 1640 medium for 30 minutes at 37°C. The lymphocytes were then washed in phosphate-buffered saline (PBS) and 0.5 × 106 cells were incubated with 100 µL plasma for 1 hour on ice. After 2 washes, the cells were incubated with FITC-conjugated F(ab)2 fragment of mouse anti-human IgG for 30 minutes on ice and fixed with 2% paraformaldehyde/PBS. Binding of PSAs to lymphocytes was analyzed by flow cytometry and the reactivity was expressed as mean fluorescence intensity (MFI).

Flow cytometry

Using 3-color flow cytometry, freshly isolated PBMCs were stained with anti-CD19–CyChrome, anti-CD27–FITC and anti-CD70–PE or anti–LAIR-1 (leukocyte-associated Ig-like receptor)–PE-labeled monoclonal Ab (PharMed, San Diego, CA) as previously described.39 According to expression of CD27, naive B cells were defined as CD19+CD27− and memory B cells as CD19+CD27+ cells.39 Flow cytometry analysis was performed with a FACSscan instrument (Becton Dickinson, Mountain View, CA) using the Cellquest software (Becton Dickinson). Forward/side scatter dot plot was used to gate the live lymphocyte population and 25 000 cells per sample were analyzed.
In order to analyze whether activated naive B cells are primed to produce IgG in vivo, peripheral B lymphocytes were purified from 3 untreated HIV-1–infected and 3 uninfected individuals. The cells were stained for surface expression of CD27 (FITC), CD70 (PE), or LAIR-1 (PE) and intracellular expression of IgG by using an anti-IgG-CyChrome-conjugated Ab (PharMingen).

**Statistical analysis**

Differences between HIV-1–infected and uninfected subjects were analyzed by Mann-Whitney test, Wilcoxon signed rank paired test, or Student t test, as appropriate. Correlation analysis between variables was performed by Spearman rank test or regression analysis. Data in the text are expressed as median and range or mean plus or minus SEM.

**Results**

**Spontaneous IgG secretion by PBMCs**

We measured in vitro spontaneous IgG secretion by PBMCs from 41 HIV-1–infected and 20 uninfected individuals. As previously reported, PBMCs from HIV-1–infected subjects spontaneously secreted a high amount of IgG as compared with healthy donors (400 ± 47 ng/mL vs 106 ± 8 ng/mL; P < .001). Interestingly, we observed a strong positive correlation between the IgG secretion by PBMCs and the absolute CD4+ T cell count (rho = 0.66, P < .001), indicating that spontaneous IgG secretion by B cells during HIV-1 infection is dependent on CD4+ T cells. This observation is in agreement with the finding that CD4+ T cells are critical in driving hypergammaglobulinemia in chronic viral infections.25

**Polyclonal B-cell activation is cell-contact dependent in HIV-1 infection**

We asked whether direct cell-cell contact or soluble mediators released by PBMCs were involved in the high IgG secretion by B cells. To this end, spontaneous in vitro IgG production was measured from the following 3 culture conditions: (1) unfractionated PBMCs; (2) purified B cells and B-cell–depleted PBMCs separated by Transwell membrane with pore size 5.0 μm in order to inhibit cell-to-cell direct interaction; and (3) purified B cells only. As indicated in Figure 1, B cells from unfractionated PBMCs secreted a significantly higher amount of IgG as compared with B cells separated from PBMCs in the Transwell plates (680 ± 102 ng/mL vs 362 ± 73 ng/mL; P < .001). In line with this observation, B cells alone produced a similar amount of IgG as produced by B cells in the Transwell plate (281 ± 39 ng/mL; P = .81). These findings indicate that polyclonal B-cell activation in HIV-1 infection is dependent on the direct contact between B lymphocytes and other cell types present in the PBMC population, which recently have been suggested to be CD4+ T cells, monocytes, and NK cells.22,40

**Activated phenotype of naive B cells in HIV-1 infection**

It has recently been described that naive B cells activated in a B-cell receptor (BCR)–independent fashion may be the source of hypergammaglobulinemia in chronic viral infections.25 We analyzed the expression of 2 activation/differentiation markers (CD70 and LAIR-1) on naive B cells from HIV-1–infected and uninfected subjects. In healthy individuals, the expression of CD70 is up-regulated in naive B cells recently stimulated by an antigen41 while the expression of LAIR-1 is down-regulated throughout the process of terminal differentiation into plasma cells.42 In the HIV-1–infected individuals we observed the appearance of a subset of naive B cells with an up-regulated expression of CD70 (4.7% ± 0.8%) that is barely detectable in healthy subjects (1.5% ± 0.4%; P = .01; Figure 2A). The percentage of CD70+ naive B cells was positively correlated with the plasma IgG (rho = 0.34, P = .02). Similarly, we also found that a significant proportion of the naive B cells from patients down-regulated the expression of LAIR-1 as compared with healthy subjects (11.1% ± 1.4% vs 2.7% ± 0.6%; P < .001; Figure 2B), suggesting that these cells are activated and more differentiated. However, the percentage of LAIR-1- or CD70+ naive B cells was not correlated to CD4+ T-cell count or HIV-1 plasma load (data not shown).

The hyperactivation status of naive B cells was also demonstrated by the finding that purified naive B cells from HIV-1–infected patients showed a 2-fold increase in spontaneous IgG production.
secretion in vitro as compared with healthy donors (277 ± 67 ng/mL vs 94 ± 34 ng/mL; *P = .06*). Interestingly, the spontaneous IgG secretion by naive B cells tended to positively correlate with the CD4⁺ T-cell count (*P = .09*), indicating that CD4⁺ T cells may be involved in priming the activation of naive B cells in HIV-1 infection. Accordingly, the spontaneous IgG secretion by cultured PBMCs from the same patients was significantly correlated with the CD4⁺ T-cell count (*r = 0.77, *P = .02*).

In order to evaluate whether naive B cells are in vivo activated and may be a cellular source of IgG production we purified B cells from 3 untreated patients and 3 donors and analyzed the intracellular content of IgG in naive B cells in relation to the expression of CD70 and LAIR-1. Interestingly, we observed that a significant proportion of naive B cells from HIV-1–infected patients carried intracellular IgG while these cells were low in healthy donors (12.9% ± 0.7% vs 3.4% ± 0.7%; *P < .001; Figure 3A,C). Among the population of CD70⁺ naive B cells (Figure 3B,D), we found that the fraction of IgG⁺ cells was higher in HIV-1–infected than in uninfected subjects (47.6% ± 2.4% vs 13.1% ± 1.9%; *P < .001). HIV-1–infected persons carried a similar proportion of IgG⁺ cells in the LAIR-1⁻naive B cells as compared with healthy donors (7.8% ± 3.5% vs 9.2% ± 0.9%; *P = NS*). These in vivo observations strongly indicate that activated naive B cells from HIV-1–infected patients may have undergone an IgM–IgG class-switch process.

**Loss of antigen-specific humoral immunity in HIV-1 infection**

The finding that activated naive B cells might contribute to the hypergammaglobulinemia prompted us to evaluate the status of serologic memory in HIV-1 infection. We have recently reported that the reduction of circulating memory B cells observed in HIV-1 infection is associated with a significant increase of spontaneous cell death in vitro of memory B lymphocytes. In the populations described here we confirm that memory B lymphocytes are reduced in HIV-1 infection as compared with uninfected controls (20% [range, 6.8%-43%] vs 34.3%, [range, 21.1%-60.7%]; *P < .001*) and that these cells exhibit higher spontaneous apoptosis as compared with the cells from healthy subjects (26.2% ± 2.5% vs 7.9% ± 1.4%; *P < .001*). Moreover, regression analysis performed on treatment-naïve patients showed that the percentage of memory B cells inversely correlates with the HIV-1 plasma viral load (*r = 0.45, *P = .02*). Here, we evaluated whether the reduction and death of memory B lymphocytes were related to decreased levels of antigen-specific Ab. Antibody levels to HIV-1 gp41, tetanus toxoid, and measles were measured. Also, functional affinity (avidity) of anti–measles antibodies (anti-M) was measured. HIV-1–infected subjects were grouped on the basis of the median percentage of memory B cells (20%) into subjects carrying normal (NM, > 20%) or low (LM, < 20%) memory B cells. Age, sex, CD4⁺ T-cell count, and treatment status were comparable between LM and NM patients (Table 1). Moreover, the absolute number of circulating memory B cells was significantly higher in NM patients (34 cells/μL [range, 13-133 cells/μL]) as compared with LM patients (9.7 cells/μL [range, 3.5-56 cells/μL]; *P < .001*).

**Anti–measles IgG antibodies**

In our cohort, we observed that the levels of anti-M antibodies were lower in HIV-1–infected subjects as compared with healthy individuals (4.92 ± 0.50 IU/mL vs 7.74 ± 1.22 IU/mL; *P = .05*; Figure 4) and were characterized by a similar avidity (50.8% ± 2.3% vs 54.1% ± 2.6%; *P = .37*). Interestingly, regression analysis performed on the population of HIV-1–infected subjects showed a correlation between the anti-M antibody levels and the percentage of memory B cells (*r = 0.52, *P < .001*). Among the infected

HIV-1–infected patients with low (LM) or normal (NM) frequency of memory B cells are indicated. The absolute number of CD4⁺ T cells is indicated in cells/μL. HIV-1 RNA is expressed as log₁₀ copies/mL and memory B cells as the percentage of the total B cells. Data are expressed as mean ± SEM or median (5-95 percentiles).
individuals, anti–measles antibodies titers in HIV-1 LM subjects (3.3
IU/mL [range, 1.12–6.68 IU/mL]) were significantly lower as compared
with the HIV-1 NM subjects (5.61 IU/mL [range, 1.06–13.36 IU/mL];
P < .04) and to healthy controls (P = .006; Figure 5A).

Anti–tetanus toxoid IgG antibodies

According to the Swedish vaccination program, all subjects in the
study had received vaccination with TT. Anti-TT antibody levels
were higher in the control group (1.604 IU/mL [range, 0.087–6.002
IU/mL]) as compared with HIV-1–infected subjects (0.624 IU/mL
range, 0.3–3.48 IU/mL); P < .01; Figure 4). HIV-1–infected subjects
with low memory B lymphocytes had a median anti-TT antibody level of 0.499 IU/mL (range, 0.2576 IU/mL) that was lower as compared with both healthy controls (P = .001) and HIV-1–infected individuals with normal memory B cells (1.006 IU/mL [range, 0.348 IU/mL]; P = .09; Figure 5B).

Anti–HIV-1 antibodies

Subjects with normal frequency of memory B cells harbored a
higher concentration of anti–HIV-1 antibodies (6.81 × 10^3 U/mL
range, 8.38 × 10^3–149 × 10^3 U/mL) as compared with subjects
with low memory B cells (3.56 × 10^3 U/mL [range, 0.19 × 10^3–71 × 10^3 U/mL]; P = .01; Figure 5C).

Polyclonal B-cell activation and naive/memory B cells

Despite the consistent reduction of antigen-specific Abs, polyclonal
B-cell activation occurred in vivo as shown by the high levels of
plasma IgG in HIV-1–infected subjects as compared with healthy
controls (15.3 ± 0.7 g/L vs 9.6 ± 0.5 g/L; P < .001; Figure 4).
Interestingly, the levels of hypergammaglobulinemia were compar-
able between HIV-1–infected subjects with normal (15.2 ± 1 g/L)
or reduced (15.4 ± 0.9 g/L) memory B cells (Figure 6A). This
finding indicates that in HIV-1 infection hypergammaglobulinemia
is observed in parallel to selective loss of antigen-specific antibod-
ies. Contrary to hypergammaglobulinemia, the reduction of spec-
ific antibodies is associated with decreased memory B lymphocytes.

In order to better define the nature of the IgG detected in HIV-1–
infected subjects and since HIV-1 infection is also characterized by
increased levels of autoantibodies, we evaluated the presence of
polyspecific self-reactive antibodies. High levels of PSA have been
detected in HIV-1 infection and these autoantibodies have been shown
to bind lymphocytes and mediate T-cell death.28 Human PSA from
HIV-1–infected subjects showed a higher reactivity (defined as MFI)
vs healthy subjects (11.8 [range, 4.6–53.9] vs 7.8 [range, 4.1–12.60; P < .01). In the HIV-1 population, the MFI of PSA was correlated to the plasma IgG (r = 0.547, P < .001) and PSA reac-
tivity was similar between HIV-1 NM subjects and HIV-1 LM subjects
(15.9 [range, 10.3–23.8] vs 7.5 [range, 7–21.6]; P = .226; Figure 6B).
Interestingly, we found that the PSA reactivity was positively
 correlated with the percentage of CD70+ naïve B lymphocytes
(r = 0.36, P < .05) but not with the proportion of LAIR-1+ naïve
B cells, further supporting the possibility that abnormally
activated naïve B cells may be responsible for the hypergamma-
oglobulinemia detected in HIV-1–infected persons.

Discussion

In the present study we have evaluated the nature of hypergamma-
globulinemia and antigen-specific antibody pattern in relation to
naive and memory B lymphocytes in HIV-1–infected subjects.

Hypergammaglobulinemia is commonly observed in autoimmune
diseases and chronic infections. Recently, it was proposed that the
hypergammaglobulinemia observed in conditions of high and persistent

![Figure 5](https://www.bloodjournal.org/)

**Figure 5. Memory B cells and specific antibodies.** Concentration of antibodies to measles (A), tetanus toxoid (B), and HIV-1 gp41 (C) in healthy controls and HIV-1–infected individuals grouped into patients with normal (NM) or low (LM) memory B lymphocytes.

![Figure 6](https://www.bloodjournal.org/)

antigen concentrations can be caused by activated naive B cells, which present viral antigens in a BCR-independent manner. 25 We observed that in HIV–1–infected subjects naive (CD27−) B lymphocytes have an activated phenotype. In fact, naive B cells from patients showed an increased expression of CD70, indicating recent antigen stimulation. 41 The hyperactivation status of naive B cells from HIV–1–infected patients is also confirmed by the down-regulated expression of LAIR-1, a differentiation antigen that is gradually lost during direct cell terminal differentiation of B lymphocytes into plasma cells. 26 In addition, we found that (1) the proportion of CD70− naive B lymphocytes is positively correlated to hypergammaglobulinemia and PSA reactivity and that (2) naive B cells from patients are able to spontaneously secrete IgG in vitro and in vivo. We also provide evidence that the naive B cells with up-regulated CD70 expression detected in HIV–1–infected patients carry a higher percentage of IgG− cells as compared with uninfected donors. These findings support the hypothesis that naive B cells activated by HIV–1 may switch to IgG 25 and produce polyclonal IgG and autoantibodies.

We also observed that the capacity of B cells from patients to release immunoglobulins in vitro was dependent on direct cell-cell contact and correlated with CD4+ T-cell count, indicating that CD4+ T cells may play a crucial role in driving abnormal B-cell differentiation in HIV–1 infection, as suggested by Hunziker and colleagues for other chronic viral infections. 25

The plasma IgG in HIV–1–infected subjects contains both anti-HIV Abs and other antibodies like PSA and autoantibodies. 38, 43 In parallel, a loss of specific humoral immunity may occur as indicated by low levels of antibodies against several pathogens, 26, 27, 24 and by the rapid loss of antigen-specific antibodies following immunization. 5, 9–11, 27 We measured antibodies to TT, a common vaccination antigen and to measles, a naturally acquired infection in our cohort, and found that the levels of IgG to both antigens were significantly reduced in HIV–1–infected individuals with low memory B cells. Interestingly, LM and NM patients carried anti-measles IgG with similar avidity indexes, indicating that the defect in anti-measles antibody is not qualitative but quantitative. A similar difference was found in the levels of anti-HIV gp41 antibodies, indicating that the low number of memory B cells was associated with loss of antibodies also against a circulating antigen.

We recently reported that memory B lymphocytes from HIV–1–infected subjects undergo spontaneous apoptosis in vitro, 6, 30 suggesting that this alteration may account for the dysfunctions in humoral immunity. Many studies have indicated a defect in the humoral immunity toward several antigens 9, 11, 26, 27 and such a defect may be due to the deletion of antigen-specific CD4+ T cells or to the loss of memory B cells. Protection against reinfections is based on the immunologic memory carried by neutralizing antibodies. Also, maternally acquired immunity is very important for the protection of the baby against life-threatening infections. Intriguingly, an increased risk of acquiring measles infection early in life was observed in infants of HIV–1–infected mothers, 45–47 in association with lower anti-measles antibody titers in the mothers. These findings and the results we report here suggest that impairment in humoral memory immunity may render HIV–1–infected persons more susceptible to infections. In line with our findings, a dysfunction of memory B cells has been suggested to explain the emergence of cytomegalovirus disease in simian AIDS. 46

The finding that the V\textsubscript{H}3 gene family is underrepresented in memory B cells from HIV–1–infected subjects 39 also supports this hypothesis. Antibodies of the V\textsubscript{H}3 family represent an important mechanism of defense against bacterial and fungal infections commonly observed during HIV–1 disease. 48, 49 Since the V\textsubscript{H}3 family encodes for about 50% of all Abs, 21 a reduction of this population indicates that the repertoire of antigen-specific Abs is compromised in HIV–1–infected patients. 49, 52 Such a mechanism could be mediated by viral proteins like gp120 or by virus-induced T-cell activation, as shown by increased CD70 expression on T cells. 6, 31

In the group of treatment-naïve patients we observed that the percentage of circulating memory B lymphocytes is inversely correlated with HIV viremia, indicating that virus-induced immune activation may directly contribute to the loss of memory B cells and to B-cell dysfunctions, as recently suggested. 24 On the other hand and perhaps simultaneously, high antigenic pressure might be a bystander driving force to activate B cells to produce polyclonal Abs. 25

The B-cell hyperactivity found in our and previous studies can be considered as a paradox since a poor B-cell response occurs in patients after immunization. We found higher levels of antigen-specific Abs in patients with normal memory B cells as compared with patients with low memory B cells. Nevertheless, NM and LM patients had comparable levels of hypergammaglobulinemia and autoantibodies (ie, PSA). Taken together, these observations strongly suggest that antigen-specific Abs do not contribute to hypergammaglobulinemia during HIV–1 infection.

The findings presented in our study may also provide new insights into the mechanisms leading to long-term humoral immunity. The generation of persistent antibody production by plasma cells has been so far explained by 2 models developed in the mouse: (1) plasma cells are long-lived cells resident in the bone marrow and provide life-long antibody production 53; and (2) plasma cells are continuously generated through the differentiation of memory B cells in the presence of residual antigens. 54 A third new intriguing mechanism of maintenance of serologic memory in the human system has been recently proposed by Bernasconi and colleagues. 55 These authors provided evidence that the polyclonal activation of human memory B cells by environmental stimuli is responsible for the maintenance of antigen-specific antibodies for a lifetime. Such polyclonal stimuli may be derived from microbial products or from bystander CD4+ T-cell help. 55 In the present study we observed that the reduction of memory B cells was related to the reduction of specific humoral immunity to 3 antigens (measles, TT, and HIV–1) to which the immune system was exposed in different manners. The continuous antigenic pressure and immune activation in HIV–1 infection may drive polyclonal activation of memory B cells, eventually leading to cell death and exhaustion of the antigen-specific memory B-cell pool. Although we do not provide direct evidence for the loss of measles- and TT-specific memory B cells, our data support the hypothesis that memory B lymphocytes are needed for the maintenance of serologic memory. 55

In conclusion, our study provides evidence that a major impairment occurs in the B-cell compartment during HIV–1 infection: From one side, activated naive B cells contribute to hypergammaglobulinemia, whereas loss of memory B cells is associated with reduced levels of antigen-specific Abs. These findings should be taken in consideration when designing and evaluating therapeutic HIV vaccines. The dysfunctions in the B-cell compartment existing in patients prior to vaccination may hamper effective vaccination and lead to additional immunologic failures.
