The FIP1L1-PDGFRA fusion tyrosine kinase in hypereosinophilic syndrome and chronic eosinophilic leukemia: implications for diagnosis, classification, and management

Jason Gotlib, Jan Cools, James M. Malone III, Stanley L. Schrier, D. Gary Gilliland, and Steven E. Coutre 

Idiopathic hypereosinophilic syndrome (HES) and chronic eosinophilic leukemia (CEL) comprise a spectrum of indolent to aggressive diseases characterized by unexplained, persistent hypereosinophilia. These disorders have eluded a unique molecular explanation, and therapy has primarily been oriented toward palliation of symptoms related to organ involvement. Recent reports indicate that HES and CEL are imatinib-responsive malignancies, with rapid and complete hematologic remissions observed at lower doses than used in chronic myelogenous leukemia (CML). These BCR-ABL–negative cases lack activating mutations or abnormal fusions involving other known target genes of imatinib, implicating a novel tyrosine kinase in their pathogenesis. A bedside-to-benchtop translational research effort led to the identification of a constitutively activated fusion tyrosine kinase on chromosome 4q12, derived from an interstitial deletion, that fuses the platelet-derived growth factor receptor-α gene (PDGFRα) to an uncharacterized human gene FIP1-like-1 (FIP1L1). However, not all HES and CEL patients respond to imatinib, suggesting disease heterogeneity. Furthermore, approximately 40% of responding patients lack the FIP1L1-PDGFRA fusion, suggesting genetic heterogeneity. This review examines the current state of knowledge of HES and CEL and the implications of the FIP1L1-PDGFRA discovery on their diagnosis, classification, and management.

Introduction

Protein biologic and clinical presentations characterize idiopathic hypereosinophilic syndrome (HES). HES is similar to other diseases given the moniker “diagnosis of exclusion,” in that limited understanding of the pathogenesis of the disease has hampered therapeutic advances. The demonstration of increased myeloblasts or clonality or the development of either granulocytic sarcoma or acute myeloid leukemia helps clarify the origin of some cases of chronic eosinophilic leukemia.1 In a subset of patients, hypereosinophilia is related to excessive secretion of eosinophilopoietic cytokines from a clonal population of lymphocytes.2 The identification of FIP1-like-1–platelet-derived growth factor receptor-α (FIP1L1-PDGFRA) in cases of HES/CEL adds to a growing list of activated fusion tyrosine kinases linked to the pathogenesis of chronic myeloproliferative disorders.3 It is unique, however, because it is the first description of a gain-of-function fusion protein resulting from a cryptic interstitial deletion between genes rather than a reciprocal chromosomal translocation. The FIP1L1-PDGFRA fusion protein transforms hematopoietic cells, and its kinase activity is inhibited by imatinib at a cellular 50% inhibitory concentration (IC50) 100-fold lower than BCR-ABL.3 Acquisition of an imatinib resistance mutation in the adenosine triphosphate (ATP)–binding domain of PDGFRα in a relapsed patient previously responsive to imatinib supports a critical role for FIP1L1-PDGFRA in the pathogenesis of disease and demonstrates that FIP1L1-PDGFRA is the therapeutic target of imatinib.3 The identification of this novel molecular target in HES and CEL patients will help refine genotype-phenotype correlations in these diseases and should aid basic research of the biologic pathways involved in eosinophil proliferation, differentiation, and signaling.

Epidemiology

HES is predominantly a disease of men (male-female ratio, 9:1) and is usually diagnosed between the ages of 20 years and 50 years.4 In one series of 50 patients, the mean age at onset was 33 years and the mean duration of disease was 4.8 years (range, 1-24 years) during the time period the patients were followed.4 Rare cases in infants and children have also been described.5-7

Current classification

In 1968 Hardy and Anderson coined the term “hypereosinophilic syndrome” to describe patients with prolonged eosinophilia of unknown cause.5 Chusid et al in 1975 used 3 diagnostic criteria for HES that are still utilized today: (1) persistent eosinophilia of 1.5 × 10^9/L (1500/mm^3) for longer than 6 months; (2) lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and (3) signs and symptoms of organ involvement.5-7

Review article

recent World Health Organization (WHO) classification, a diagnosis of HES or CEL requires exclusion of reactive causes of eosinophilia (Table 1), malignancies in which eosinophilia is reactive (Table 1) or part of the neoplastic clone, and T-cell disorders associated with abnormalities of immunophenotype and cytokine production, with or without evidence of lymphocyte clonality.\(^\text{10}\) CEL has traditionally been distinguished from HES by eosinophilia (Table 1), malignancies in which eosinophilia is a sign of HES or CEL requires exclusion of reactive causes of eosinophilia.

One method for establishing a diagnosis of CEL is demonstration of eosinophil clonality; however, this is frequently not assessed or is difficult to confirm. Methods for demonstrating clonality include fluorescence in situ hybridization\(^\text{11}\) or cytogenetic analysis of purified eosinophils\(^\text{12}\) and, also, X chromosome inactivation analysis in women.\(^\text{13,14}\) X inactivation–based assessment of clonality is of limited value in HES because most patients are male. To avoid the emphasis placed on demonstrating clonality of eosinophils, Brito-Babapulle has advocated that, in cases of clonal eosinophilia, it is sufficient to demonstrate only that eosinophils are part of a clonal bone marrow disorder and not necessarily part of the malignant clone, with treatment tailored to the underlying disease.\(^\text{15}\) In this scheme, blood eosinophilia is divided into 3 categories: reactive (nonclonal eosinophilia), clonal disorders of the bone marrow associated with eosinophilia, and HES, which remains a diagnosis of exclusion.\(^\text{15}\)

Prior reviews have discussed the difficulty in using abnormal eosinophil morphology (eg, cytoplasmic hypogranularity or vacuolization, abnormal lobation, ring nuclei) to reliably distinguish reactive from clonal eosinophilia because these cytologic changes may be present in both conditions.\(^\text{15-17}\) Roufosse et al have proposed that disease presentations with CML-like features be segregated into a “myeloproliferative variant” of HES.\(^\text{18}\) Clinical and laboratory features associated with this variant include hepatomegaly, splenomegaly, anemia, thrombocytopenia, bone marrow dysplasia or fibrosis, and elevated levels of cobalamin. This is in contrast to a “lymphocytic variant” or T-cell–mediated HES (discussed in “T-cell–mediated HES”), which typically follows a more benign course and is usually manifested primarily by skin disease.\(^\text{18}\) Some patients exhibit overlapping characteristics of both variants. Although such groupings may correspond to biologic subsets of HES, evaluation of a large cohort of patients is required to validate their prognostic relevance.

Clinicopathologic manifestations

In one large series, eosinophilia was discovered incidentally in 12% of patients.\(^\text{4}\) The most common presenting signs and symptoms were weakness and fatigue (26%), cough (24%), dyspnea (16%), myalgias or angioedema (14%), rash or fever (12%), and rhinitis (10%).\(^\text{4}\) Table 2 shows the cumulative frequency of organ involvement in 105 patients previously compiled from 3 series.\(^\text{4,17,19-21}\)

Hematologic findings

Although persistent eosinophilia without a clinically identifiable cause is the sine qua non of HES, the hematologic picture can vary. Relatively modest elevations in the leukocyte count (eg, 20-30 × 10⁹/L [20 000-30 000/mm³]) with peripheral eosinophilia in the range of 30% to 70% are commonly observed,\(^\text{5}\) but significantly higher leukocyte counts have also been reported.\(^\text{19,20}\) Neutrophilia, basophilia, myeloid immaturity, and both mature and immature eosinophils with varying degrees of dysplasia may be found in the peripheral blood or bone marrow.\(^\text{19,22}\) In one series, anemia was present in 53% of patients, thrombocytopenia was more common than thrombocytosis (31% versus 16%), and bone marrow eosinophilia ranged from 7% to 57% (mean, 33%).\(^\text{22}\) Charcot-Leyden crystals were frequent marrow findings, whereas increased blasts and myelofibrosis were less often observed.\(^\text{22}\)

Cardiac disease

The multistep process of cardiac injury illustrates some of the pathophysiologic mechanisms contributing to organ damage in HES (previously reviewed by Fauci et al\(^\text{23}\) and Weller and Bubley\(^\text{24}\)). In the initial necrotic stage, cardiac disease may be initiated by eosinophil damage to the endocardium, with local platelet thrombus subsequently leading to formation of mural thrombi that have the potential to embolize (thrombotic stage). The contents of eosinophil granules, including major basic protein and eosinophilic
cationic protein, may promote endothelial damage and hypercoagulability, enhancing the thromboembolic risk.\textsuperscript{23,24} In the later fibrotic stage, organization of thrombus can lead to fibrous thickening of the endocardial lining and, ultimately, restrictive cardiomyopathy.\textsuperscript{2,21} Valvular insufficiency in HES is commonly related to mural endocardial thrombosis and fibrosis involving leaflets of the mitral or tricuspid valves.\textsuperscript{25-27} Table 2 lists manifestations of HES that have been reported in hematologic, cardiac, and other organ systems.

**T-cell–mediated HES**

A proportion of HES cases exhibit expansion of abnormal lymphocyte populations. Immunophenotypic features include double-negative, immature T cells (eg, CD3\textsuperscript{−}CD4\textsuperscript{−}CD8\textsuperscript{−}) or absence of CD3 (eg, CD3\textsuperscript{−}CD4\textsuperscript{+}CD8\textsuperscript{−}), a normal component of the T-cell receptor complex.\textsuperscript{91-93} In patients with T-cell–mediated hypereosinophilia with elevated immunoglobulin E (IgE) levels, lymphocyte production of interleukin-5 (IL-5) and in some cases IL-4 and IL-13—suggests that these T cells have a helper type 2 (Th2) cytokine profile.\textsuperscript{18,91-93,95} In a study of 60 patients recruited primarily from dermatology clinics, 16 had a unique population of circulating T cells with an abnormal immunophenotype.\textsuperscript{2} Clonal rearrangement of T-cell receptor genes was demonstrated in half of these individuals (8 of 60 total patients). The abnormal T cells secreted high levels of interleukin-5 in vitro and displayed an activated immunophenotype (eg, CD25 and/or HLA-DR expression). One patient during study and 3 at follow-up were diagnosed with T-cell lymphoma or Sézary syndrome, indicating that T cells in some HES patients have neoplastic potential. The factors that contribute to malignant transformation in T-cell–associated HES require further characterization. In some cases, accumulation of cytogenetic changes in T cells and proliferation of lymphocytes with the CD3\textsuperscript{−}CD4\textsuperscript{+}CD8\textsuperscript{−} phenotype have been observed.\textsuperscript{95-97} It is currently unknown whether subsets of T-cell–associated HES cases also express the FIP1L1-PDGFR\textalpha fusion.

**Cytogenetic and molecular features of hematologic malignancies with eosinophilia**

Several hematologic malignancies are associated with eosinophilia. Eosinophilia is thought to result from the production of cytokines (eg, IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor [GM-CSF]) from malignant cells in T-cell lymphomas,\textsuperscript{98} Hodgkin disease,\textsuperscript{99} and acute lymphoblastic leukemias.\textsuperscript{100,101} In some cases, isolated eosinophilia may herald the initial diagnosis or relapse of these conditions.

Over the last 3 decades, the list of chromosomal abnormalities in cases reported as HES or CEL has grown (reviewed by Bain\textsuperscript{102}). However, a unique clonal karyotype has not been associated with these diseases, and most patients exhibit a normal karyotype by conventional cytogenetics. Although trisomy 8 is frequently detected in these eosinophilic disorders,\textsuperscript{103-108} it is also observed in other hematologic malignancies. Three HES case reports have described balanced reciprocal translocations within or near the chromosome 4q12 locus of the PDGFR\textalpha and KIT tyrosine kinases: t(3;4)(p13;q12),\textsuperscript{107} t(4;7)(q11;q32),\textsuperscript{108} and t(4;7)(q11:p13).\textsuperscript{109} The genes involved in these translocations were not identified. In a recent report, a 6-year-old girl with hypereosinophilia presented with a t(5;9)(q11;q34) constitutional translocation, involving genes for the ABL tyrosine kinase and possibly granzyyme A on chromosome 5.\textsuperscript{7} In this case, no mention was made of the use of imatinib.

Eosinophils have been found to be part of the malignant clone in systemic mastocytosis,\textsuperscript{110} CML and other chronic myeloproliferative disorders (MPDs), and in specific subtypes of acute myeloid leukemia (AML). The best-characterized examples in the French-American-British classification of AML are M4Eo inv(16)(p13q22) or t(16;16)(p13;q22),\textsuperscript{111} resulting in chimeric fusion of the CBF\textbeta and MLL\textit{1} genes, and M2 t(8;21)(q22;q22),\textsuperscript{112} which links the AML-1 and ETO genes. Other abnormal karyotypes reported in AML with eosinophilia include monosomy 7,\textsuperscript{113} trisomy 1,\textsuperscript{1,14} t(10;11)(p14;q21),\textsuperscript{1,15} t(5;16)(q33;q22),\textsuperscript{116} and t(16;21)(p11;q22).\textsuperscript{117}
The latter 2 may represent chromosome 16 variants with an underlying cryptic fusion gene. Eosinophil clonality has been demonstrated in cases of eosinophilic myelodysplastic syndrome (MDS) with t(1;7) or dic(1;7) karyotypes.\(^\text{11,18}\) Eosinophilia is also a feature of acute and chronic hematologic malignancies with rearrangements involving transcription factor ETV6 (ETV6 translocation variant 6, TEL) on chromosome 12p13. Examples include the ETV6-ABL fusion in t(9;12)(q34;p13) AML,\(^\text{119}\) and also, the small subset of chronic myelomonocytic leukemia patients with t(5;12)(q33;p13), which fuses platelet-derived growth factor receptor-beta (PDGFRB) on chromosome 5q33 to ETV6.\(^\text{120}\) In this latter disease, imatinib produces clinical remissions by inhibiting the deregulated activity of the fusion tyrosine kinase.\(^\text{121}\) Proliferation of eosinophils in some AML, MPD, and MDS cases is associated with rearrangements involving the long arm of chromosome 5 (eg, 5q31-33) where several genes encoding eosinophilic cytokines reside.\(^\text{122-124}\) In a study of 9 patients with MPD or mixed MDS/MPD and a translocation involving 5q31-33, fluorescence in situ hybridization (FISH) unmasked disruption of the PDGFRB gene in 6 cases.\(^\text{125}\) The translocations included t(1;5)(q32;q33), t(1;5)(q22;3q31), t(1;3;5)(p36;p21;q33), t(2;12;5)(q37;2q21;3q1), and t(5;14)(q33;q24). Eosinophilia was noted in 3 of these patients and noted in an additional patient at the time of transformation to AML.\(^\text{125}\) Recent cloning of the t(1;5)(q23;q33) breakpoint revealed that PDGFRB is fused to the novel partner protein myomoglobin.\(^\text{126}\) In a subset of B-cell acute lymphoblastic leukemias, translocation of the IL-3 gene on chromosome 5q31 to the immunoglobulin heavy chain gene on chromosome 14q32 is typically associated with eosinophilia.\(^\text{127}\) In the “stem cell” myeloproliferative disorders, mutation in a pluripotent hematopoietic progenitor results in a spectrum of diseases including T- or B-cell lymphoblastic lymphoma, bone marrow myeloid hyperplasia, and eosinophilia. These poor-prognosis disorders are related to recurrent breakpoints on chromosome 8p11 that involve translocation of the fibroblast growth factor receptor 1 (FGFR1) gene to 5 currently identified partner loci: FOP at 6q27,\(^\text{128}\) CEP110 at 9q33,\(^\text{129}\) FIM/ZNF198 at 13q12,\(^\text{130}\) BCR at 22q11,\(^\text{131}\) and the human endogenous retrovirus gene (HERV-K) at 19q13.\(^\text{132}\) Before attributing eosinophilia to HES or CEL, these various hematologic malignancies should be given diagnostic consideration.

### Prognosis

A prior review of 57 HES cases included reports published between 1919 and 1973.\(^\text{9}\) The median survival was 9 months, and the 3-year survival was only 12%.\(^\text{9}\) These patients generally had advanced disease, with congestive heart failure accounting for 65% of the identified causes of death at autopsy. In addition to the development of cardiac disease, peripheral blood blasts or a white blood cell (WBC) count more than 100 × 10^9/L (100 000/mm^3) were associated with a poor prognosis.\(^\text{9}\) A later report of 40 HES patients observed a 5-year survival rate of 80%, decreasing to 42% at 15 years.\(^\text{20}\) In this cohort, poor prognostic factors included the presence of a concurrent myeloproliferative syndrome, lack of response of the hypereosinophilia to corticosteroids, existence of cardiac disease, male sex, and the height of eosinophilia.\(^\text{20}\) Modern diagnostic methods and better treatment for cardiovascular disease probably contribute to improved survival.

### Current treatment

In patients with persistent eosinophilia and organ damage due to reactive causes or clonal bone marrow disease, therapy should be directed to the underlying disorder. Some treatment algorithms have incorporated serial monitoring of eosinophil counts, evaluation of clonality (eg, T-cell–receptor gene rearrangement, immunophenotyping), bone marrow aspiration and biopsy with cytogenetics, and directed organ assessment (eg, echocardiography) to identify occult organ disease and alternative causes of eosinophilia that may slowly emerge after an initial diagnosis of HES.\(^\text{15,21}\) In patients with HES, corticosteroids (1 mg/kg/d) are indicated for organ disease and are useful for eliciting rapid reductions in the eosinophil count.\(^\text{4,21,130}\) Lack of steroid responsiveness warrants consideration of cytotoxic therapy. Hydroxyurea is an effective first-line chemotherapeutic for HES\(^\text{4,21,132,133}\); some benefit has also been reported for second-line agents including vincristine,\(^\text{134-136}\) pulsed chlorambucil,\(^\text{137}\) cyclophosphamide,\(^\text{137}\) and etoposide.\(^\text{138,139}\) Interferon-α (IFN-α) can elicit long-term hematologic and cytogenetic responses in HES and CEL patients resistant to other therapies, including prednisone and hydroxyurea.\(^\text{109,140-145}\) Some have advocated its use as initial therapy for these diseases.\(^\text{144}\) Remissions have been associated with improvement in clinical symptoms and organ disease, including hepatosplenomegaly, cardiac and thromboembolic complications, mucosal ulcers, and skin involvement.\(^\text{145}\) IFN-α exerts pleiotropic effects including inhibition of eosinophil proliferation and differentiation.\(^\text{146}\) Inhibition of IL-5 synthesis from CD4⁺ helper T cells may be relevant to its mode of action in T-cell–mediated forms of HES.\(^\text{147}\) IFN-α may also act more directly via IFN-α receptors on eosinophils, suppressing release of mediators including cationic protein, neurotoxin, and interleukin-5.\(^\text{148}\) Responses to cyclosporin A\(^\text{149,150}\) and 2-chlorodeoxyadenosine have also been reported in HES.\(^\text{151}\)

Bone marrow/peripheral blood stem cell allogeneic transplantation has been attempted in patients with aggressive disease. Disease-free survival ranging from 8 months to 5 years has been reported\(^\text{152-156}\) with one patient relapsing at 40 months.\(^\text{157}\) Allogeneic transplantation using nonmyeloablative conditioning regimens has been reported in 3 patients, with remission duration of 3 to 12 months at the time of last reported follow-up.\(^\text{158,159}\) Despite success in selected cases, the role of transplantation in HES is not well established. Transplantation-related complications including acute and chronic graft versus host disease as well as serious infections have been frequently observed.\(^\text{160,161}\)

Advances in cardiac surgery have extended the life of patients with late-stage heart disease manifested by endomyocardial fibrosis, mural thrombosis, and valvular insufficiency.\(^\text{4,21}\) Mitral and/or tricuspid valve repair or replacement\(^\text{36,35-37,162}\) and endomyocardectomy for late-stage fibrotic heart disease\(^\text{37,163}\) can improve cardiac function. Bioprosthetic devices are preferred over their mechanical counterparts because of the reduced frequency of valve thrombosis.

Leukapheresis can elicit transient reductions in high eosinophil counts but is not an effective maintenance therapy.\(^\text{164-166}\) Similar to other myeloproliferative disorders, splenectomy has been performed for hypersplenism-related abdominal pain and splenic infarction but is not considered a mainstay of treatment.\(^\text{19,167}\) Anticoagulants and antiplatelet agents have shown variable success in preventing recurrent thromboembolism.\(^\text{19,47,30,168}\)
Imatinib in HES

Table 3 summarizes published case reports and series of patients with hematologic malignancies associated with eosinophilia who were treated with imatinib. The first case of imatinib treatment in HES was reported in 2001. The patient was resistant or intolerant to prior therapies including corticosteroids, hydroxyurea, and IFN-α. He was treated with imatinib based on the drug’s efficacy in CML, with the hypothesis that the 2 diseases may share a common pathogenetic mechanism. The patient achieved a rapid and complete hematologic remission after taking 100 mg imatinib daily for 4 days. Complete disappearance of peripheral eosinophils occurred by day 35. Imatinib was decreased to 75 mg daily for headaches, which still effectively controlled eosinophil levels.

A subsequent report included 5 HES patients treated with 100 mg imatinib daily. Four male patients with normal serum levels of interleukin-5 achieved complete hematologic remissions. One female patient with high levels of serum interleukin-5 did not respond to imatinib. All patients who responded were able to discontinue other treatments.

A third report described a 54-year-old man with HES and organ involvement including splenomegaly, skin, cardiac, and central nervous system disease. He was resistant to steroids and chemotherapy, including 2-chlorodeoxyadenosine and cytosine arabinoside. Before treatment, the WBC count was 9.7 × 10^9/L (9700/mm^3) with 68% eosinophils. After 18 days of imatinib (100 mg daily), the patient achieved a complete hematologic remission with a WBC count of 3.9 × 10^9/L (3900/mm^3) and 0% eosinophils. His hematologic response was accompanied by marked symptomatic improvement.

Another study reported the efficacy of 100 to 400 mg imatinib daily in 5 HES patients and 2 patients with a diagnosis reported as eosinophilia-associated chronic myeloproliferative disorder (eos-CMD). At a median follow-up of 17 weeks, 1 eos-CMD and 2 HES patients achieved complete clinical remissions, and an additional HES patient achieved a partial remission. Screening for known targets of imatinib, including BCR-ABL, or mutations in the coding exons of KIT and PDGFRB was negative. In contrast to the earlier report where complete remittters had normal serum interleukin-5 levels, the current group of responders had high serum levels. These disparate findings demonstrate that levels of this eosinophil-stimulating cytokine are not necessarily predictive of imatinib responsiveness in HES patients. Although imatinib was generally well tolerated, one responding HES patient experienced cardio-venous shock within the first week of treatment with a marked decrease in the left ventricular (LV) ejection fraction. Endomyocardial biopsy revealed eosinophilic myocarditis with evidence of eosinophil infiltration, degranulation, and myocyte damage. The patient was successfully treated with high-dose corticosteroids. LV function recovered, and the patient was restarted on imatinib and achieved a hematologic remission. More data are needed to evaluate the role of prophylactic steroids in HES patients with cardiac disease who receive imatinib treatment.

An additional cohort of 9 symptomatic HES patients (6 male; median age, 50) was treated with imatinib starting at 100 mg daily. They had received an average of 3 prior therapies. With median follow-up of 13 weeks, 4 male patients achieved a complete remission. Three exhibited response within the first 2 weeks of therapy, while the fourth required a dose increase to 400 mg daily at day 28 to attain a normal eosinophil count. Overall, treatment was well tolerated, with primarily grade 1 toxicities previously associated with imatinib reported.

The largest study described 16 patients, including 11 treated with imatinib. At presentation, the median eosinophil count was 14.5 × 10^9/L (14500/mm^3) (range, 4.96 × 10^9/L to 53 × 10^9/L [4960/mm^3 to 53000/mm^3]). Nine of the treated patients had normal karyotypes. One CEL patient had a clonal cytogenetic abnormality t(1;4)(q44;q12), and one patient with AML arising from CEL had a complex karyotype, including trisomies 8 and 19, add2q, and del6q. Hematologic responses were observed in 10 of 11 HES patients treated with imatinib at doses of 100 to 400 mg daily. The median time to response was 4 weeks (range, 1 to 12 weeks). Nine of the 10 patients demonstrated sustained hematologic responses (lasting at least 3 months), with a median duration of 7 months at the time of publication (range, 3 to 15 months). One patient had a transient response lasting several weeks and failed to derive benefit from an increase in the imatinib dose. Figure 1 shows a bone marrow biopsy from the CEL/AML patient with the

†FIP1L1-PDGFRA fusion not assessed.
complex karyotype before imatinib treatment and at the time of hematologic remission following 3 months of therapy.

The molecular basis for response in most patients was inhibition of a novel fusion tyrosine kinase, FIP1L1-PDGFRA, in which a newly described human gene, FIP1-like-1 (FIP1L1), is fused to the gene encoding platelet-derived growth factor receptor-\(\alpha\) (PDGFRA).\(^3\) The FIP1L1 gene encodes a protein that is homologous to a previously characterized Saccharomyces cerevisiae protein, Fip1, a synthetic lethal component of the mRNA polyadenylation apparatus.\(^173\) The fusion gene is generated by an interstitial deletion on chromosome 4q12 rather than a reciprocal translocation.\(^3\) FIP1L1-PDGFR\(\alpha\) was present in 9 (56%) of 16 HES patients. In patients for whom FIP1L1-PDGFR\(\alpha\) testing was performed, the fusion was detected with a similar frequency in treated (5 of 10) and untreated (4 of 6) patients.\(^3\) All 5 patients with the FIP1L1-PDGFR\(\alpha\) fusion responded to imatinib.\(^3\) However, an additional 4 patients with durable responses to imatinib lacked FIP1L1-PDGFR\(\alpha\), indicating that an as yet unidentified target of imatinib is responsible for HES in these cases.\(^3\) To date, no primary treatment failures to imatinib have been reported in patients with the FIP1L1-PDGFR\(\alpha\) fusion.

The FIP1L1-PDGFR\(\alpha\) genotype may cosegregate with a clinical phenotype including myeloproliferative-like HES (HES-MPD), tissue fibrosis, and increased serum tryptase levels.\(^174-177\) The FIP1L1-PDGFR\(\alpha\) fusion was identified in all 7 HES-MPD patients with elevated serum tryptase levels (all were treated with imatinib and responded)\(^177\): in an earlier companion study, the fusion was not detected in 4 HES patients with normal serum tryptase or 2 patients with familial eosinophilia. FIP1L1-PDGFR\(\alpha\) may also be related to the pathogenesis of eosinophilic subsets of systemic mastocytosis (SM). Deletion of the CHIC2 locus, a surrogate for the FIP1L1-PDGFR\(\alpha\) fusion, was detected in imatinib-responsive patients diagnosed with systemic mastocytosis (SM) and eosinophilia but not in 2 other patients with SM and the KIT Asp816Val (D816V) mutation who exhibited no response to imatinib.\(^176\)

Currently, limited data are available regarding imatinib’s ability to reverse eosinophil-related organ damage. Among 3 HES-MPD patients with endomyocardial fibrosis and congestive heart failure, there was no improvement in cardiac disease despite complete hematologic responses to imatinib.\(^177\) However, significant improvement of respiratory symptoms associated with clearing of interstitial infiltrates on chest computed tomography (CT)\(^171,175\) and normalization of pulmonary function testing have been reported.\(^175\) We and others have demonstrated reversal of myelofibrosis (Figure 1).\(^175\)

**Molecular biology of FIP1L1-PDGFR\(\alpha\)**

The FIP1L1-PDGFR\(\alpha\) fusion gene is created by the del(4)(q12q12), an 800-kb deletion on chromosome 4q12 (Figure 2).\(^3\) The deletion is not visible using standard cytogenetic banding techniques and explains why most HES patients with the fusion have an apparently normal karyotype. One imatinib-responsive HES patient with a t(1;14)(q44.q12) ultimately led to the identification of the fusion gene, but in retrospect the translocation was merely a “stalking horse” for the del(4)(q12q12) that gives rise to the fusion gene.\(^3\) The deletion disrupts the FIP1L1 and PDGFR\(\alpha\) genes and fuses the 5’ part of FIP1L1 to the 3’ part of PDGFR\(\alpha\).\(^3\) In each patient the breakpoints in FIP1L1 and PDGFR\(\alpha\) are different, but the FIP1L1-PDGFR\(\alpha\) fusions are always in frame.\(^3\) The breakpoints in FIP1L1 are scattered over a region of 40 kb (introns 7-10), whereas the breakpoints in PDGFR\(\alpha\) are restricted to a very small region that invariably involves PDGFR\(\alpha\) exon 12.\(^3\) As the 5’ part of exon 12 of PDGFR\(\alpha\) is deleted, splicing of FIP1L1 exons to the truncated exon 12 of PDGFR\(\alpha\) occurs by use of cryptic splice sites within exon 12 of PDGFR\(\alpha\) or in introns of FIP1L1 (Figure 3).\(^3,175\)

FIP1L1-PDGFR\(\alpha\) has also been discovered in the cell line EOL-1, derived from a patient with acute eosinophilic leukemia following hyperesinophilic syndrome. Imatinib and 2 other inhibitors of PDGFR\(\alpha\), vatalanib and THRX-165724, reduced the viability of EOL-1 cells and a prominent 110-kDa phosphoprotein, ultimately identified as FIP1L1-PDGFR\(\alpha\).\(^177\)

FIP1L1 is a 520–amino acid protein that contains a region of homology to Fip1, a yeast protein with synthetic lethal function that is involved in polyadenylation.\(^174,178\) Similar proteins are found in plants, worm, fly, rat, and mouse. All share the well-conserved 42–amino acid “Fip1” motif (pfam domain no. PF05182; http://pfam.wustl.edu/cgi-bin/getdesc?acc=PF05182), which is also present in the FIP1L1-PDGFR\(\alpha\) fusion protein. The exact function of the human or mouse FIP1L1 protein is not known. Based on the abundance of FIP1L1 expressed sequence tags (ESTs) in the databases that are derived from different tissues and cell types, FIP1L1 is predicted to be under the control of a ubiquitous promoter.
kinases, including BCR-ABL, TEL-PDGFR based on analysis of structure-function in all known fusion tyrosine kinase activity is not well understood. It would be predicted, in an HES case by interphase FISH using the BAC probes shown in panel B. Absence indicates centromeric side; and tel, telomeric side. (C) Detection of the del(4)(q12q12) probes (RPCI11-120K16, RPCI11-3H20, and RPCI11-24O10) are indicated. cen/H11032 to the 3 genes. The 800-kb deletion, resulting in the fusion of the 5 PDGFRA, part of 3 bacterial arti.

Figure 2. Fusion of FIP1L1 to PDGFR. (A) Schematic representation of the FIP1L1, PDGFRα, and FIP1L1-PDGFRα fusion proteins. NLS indicates nuclear localization signal; TM, transmembrane region; and JM, juxtamembrane region. (B) Schematic representation of the 4q12 chromosomal region around the localization signal; TM, transmembrane region; and JM, juxtamembrane region. (A) Splicing of exon 11 to exon 12 as it occurs in wild-type PDGFRα. (B) Splicing of FIP1L1 exons to the truncated exon 12 of PDGFRα as observed in 2 different HES patients. As the normal splice site in front of exon 12 is deleted, cryptic splice sites in the intron of FIP1L1 (as in case a) or within exon 12 (as in case b) are used to generate in-frame FIP1L1-PDGFRα fusions. As a result, the fusion protein sometimes contains a few extra amino acids derived from an intronic sequence of FIP1L1 (as in case a). Sequences from FIP1L1 are shown in lowercase letters and in gray; PDGFRα sequences are shown in capital letters and in black. Introns are depicted as lines; exons are shown as blocks. Splice sites are underlined in the sequence. The spliced RNA sequence and corresponding protein sequence are shown under the DNA. Cryptic splice sites are indicated with an arrow. Arrowheads indicate where the breakpoints are located in exon 12 of PDGFRα in cases a and b.

The genetic analysis of multiple patients may provide a clue to the mechanism of activation. Most chromosomal translocations that result in fusion tyrosine kinases occur at highly variable locations within large introns. Although the genomic breakpoint is in essence unique for each patient, RNA splicing usually results in expression of identical fusion proteins. Consistent with this experience, the FIP1L1 genomic breakpoints are variable and may occur in several introns within the gene. However, the genomic breakpoints in PDGFRα are quite unusual, in that they all occur within exon 12.

How might conserved breakpoints within exon 12 contribute to constitutive activation of the PDGFRα kinase? Exon 12 of PDGFRα encodes a portion of the juxtamembrane domain that is known to serve an autoinhibitory function in the context of other receptor tyrosine kinases. Disruptions of this domain by missense mutations, in-frame insertions, or in-frame deletions result in constitutive activation of the respective tyrosine kinase. For example, juxtamembrane internal tandem duplications in FLT3 result in its constitutive activation in approximately 25% of cases of AML. Mutation of the juxtamembrane region of PDGFRβ contains a WW domain with an inhibitory function for kinase activity, and in-frame point mutations of the WW domain result in constitutive activation of the kinase. Furthermore, mutations in the WW domain of PDGFRα were identified in rare cases of gastrointestinal stromal cell tumors. To date, all cloned FIP1L1-PDGFRα fusion genes result in a truncation of PDGFRα within the WW domain, suggesting that disruption of the WW domain contributes to the activation of FIP1L1-PDGFRα. Thus, a plausible hypothesis is that disruption of PDGFRα exon 12 within the WW domain, in combination with unregulated expression from the FIP1L1 promoter, are the pivotal events required for transformation of cells.

There are several important implications from the hypothesis that the interstitial deletion serves primarily to disrupt the autoinhibitory domain and fuses the kinase to a constitutively activated
and unregulated promoter. First, it indicates that potential kinase gene partners need not have dimerization motifs but only an active promoter to contribute to pathogenesis of disease. Thus, deletions of varying sizes that each disrupt exon 12 of PDGFRα could involve a spectrum of genomically diverse genes 5’ of the kinase. This mechanism could even be invoked for very large and highly variable deletions. In imatinib-responsive HES without a detectable FIP1L1-PDGFRα fusion, it will be important to analyze other potential partners for PDGFRαs as well as similar mechanisms of activation of the other known imatinib-responsive tyrosine kinases.

Another important implication of these findings is that small interstitial chromosomal deletions that activate tyrosine kinases may also occur in other hematologic malignancies or solid tumors. Indeed, it is possible that the FIP1L1-PDGFRα fusion gene itself could be expressed in tumors from other tissue types. This hypothesis can be tested using modern techniques for high-density comparative genomic hybridization, among other strategies, to search for subcytogenetic deletions in the 5’ flanking region of all known receptor tyrosine kinases. It is also possible that small interstitial deletions can engender gain-of-function oncogenes involving other classes of genes. Efforts to identify such deletions in all tumor types is warranted, in part because there are convincing data that gain-of-function fusion proteins are candidates for molecularly targeted therapies such as imatinib.

One patient who initially responded to imatinib relapsed with an acquired T674I substitution in the PDGFRα kinase domain of the FIP1L1-PDGFRα fusion. The mutation confers resistance to imatinib in vitro and in vivo. Development of resistance due to point mutation is not unexpected given the experience with imatinib in therapy of CML and CML blast crisis. We hypothesized that selective small-molecule inhibitors of PDGFRαs that have a different chemical structure than imatinib might be able to overcome resistance to imatinib in this context. We have demonstrated that an alternative PDGFRα inhibitor, PKC412, is an effective inhibitor of the imatinib-resistant FIP1L1-PDGFRα T674I mutant both in vitro and in vivo. These observations provide proof of principle that one strategy to preclude or overcome resistance mutations may be to use combinations of selective tyrosine kinase inhibitors that do not have overlapping toxicities.

The basis for the apparent lineage predilection of FIP1L1-PDGFRα for eosinophils is not well understood. No data have been reported regarding expression of FIP1L1 in eosinophils from healthy individuals. The FIP1L1-PDGFRα fusion has been detected in enriched eosinophils, neutrophils, and mononuclear cells by FISH and reverse transcriptase-polymerase chain reaction (RT-PCR) in a patient with a diagnosis of systemic mast cell disease and eosinophilia, consistent with acquisition of the rearrangement in an early hematopoietic progenitor. It is possible that it is present in all myeloid lineages but that eosinophils are particularly sensitive to the FIP1L1-PDGFRα proliferative signal. Data that would support this include neutrophilia observed in many HES patients and elevated tryptase indicative of mast cell involvement. It will also be important to evaluate lymphoid lineage involvement of FIP1L1-PDGFRα, especially in those patients with T-cell clonality associated with HES. Each of these questions can be addressed with the molecular tools now in hand.

The presence of the FIP1L1-PDGFRα fusion gene as a consequence of deletion can be used both to predict response to imatinib and to monitor response to therapy. We have developed sensitive RT-PCR-based assays for this purpose as well as FISH probes to reliably detect the deletion (Figure 2B-C). In a recent report, molecular remission was documented by PCR testing of the peripheral blood in 5 of 6 patients diagnosed with HES-MPD after 1 to 12 months of 400 mg imatinib daily.

Implications of FIP1L1-PDGFRα for the diagnosis, classification, and treatment of eosinophilic disorders

In the WHO classification, eosinophil clonality or the presence of another clonal marker distinguishes CEL from HES. However, the report by Cools et al indicates that FIP1L1-PDGFRα gene fusions can be identified in both HES and CEL patients, in contradistinction to their WHO classification as separate disorders. In light of these findings, a reappraisal of the WHO scheme for these eosinophilic diseases may ultimately be warranted. Given the early state of knowledge about FIP1L1-PDGFRα, any attempt at classification at this time would be considered preliminary, because additional data on prevalence, clinicopathologic correlates, and genetics will be important. However, based on available information, a tentative schema can be considered to help with clinical decision making and to provide a platform for addressing critical questions regarding classification.

It may be useful to consider the implications of the FIP1L1-PDGFRα fusion within a recently proposed framework that classifies blood eosinophilia as reactive, clonal, and HES. One possible approach for evaluating hypereosinophilia in the context of the FIP1L1-PDGFRα discovery is presented in Figure 4. In patients whose workup is negative for secondary causes of eosinophilia, screening for the FIP1L1-PDGFRα gene fusion could subsequently be undertaken using either RT-PCR or interphase/metaphase FISH. Patients positive for the fusion (and with fewer than 20% marrow blasts) could be classified into one clonal category of blood eosinophilia, “FIP1L1-PDGFRα-positive chronic eosinophilic leukemia” (F-P CEL, Figure 4A). Similar to cases of BCR-ABL–positive CML, F-P CEL patients would be predicted to have a high hematologic response rate to imatinib. Based on the limited number of patients evaluated, this group currently accounts for 50% to 60% of all HES/CEL cases. However, a more accurate estimate of the proportion of F-P CEL patients will require screening larger numbers of individuals with idiopathic hypereosinophilia. The recent description of the FIP1L1-PDGFRα fusion in 3 patients with a diagnosis of SM and eosinophilia indicates that the fusion may occur in a spectrum of clonal bone marrow disorders associated with eosinophilia and may not strictly define a subset of chronic eosinophilic leukemias per se. New classifications will need to reconcile such genotype-phenotype variations among patients positive for the FIP1L1-PDGFRα fusion.

Patients without reactive eosinophilia and a negative screen for the FIP1L1-PDGFRα gene fusion could be potentially categorized into 1 of at least 3 diagnostic groups (Figure 4A). FIP1L1-PDGFRα-negative patients with a clonal cytogenetic abnormality, clonal eosinophils, or increased marrow blasts (5%–19%) could be categorized as “CEL, unclassified.” FIP1L1-PDGFRα–negative patients without any of these clonal features or without increased marrow blasts could be assigned to the diagnostic group “HES.” A third group, designated “T-cell–associated HES,” would consist of HES patients in whom an abnormal T-cell population is demonstrated. Such diagnostic groups may not be mutually exclusive in all cases. Instances may arise in which CEL patients with the FIP1L1-PDGFRα fusion have another clonal marker and/or an
HES that progress to T-cell lymphoma or Se

Figure 4. Possible diagnostic and treatment algorithm for hypereosinophilia.
(A) Patients whose workup is negative for secondary causes of eosinophilia
subsequently undergo testing for the FIP1L1-PDGFRα gene fusion. Patients positive
for the fusion are classified as having one of three categories of FIP1L1-PDGFRα-positive
(F-P+)
clonal eosinophilia (eg, F-P+ chronic eosinophilic leukemia [CEL] or F-P+
 systemic mastocytosis [SM] with eosinophilia). A negative test for the fusion would
classify patients into 1 of 3 diagnostic groups based on additional laboratory criteria:
CEL, unclassified; hypereosinophilic syndrome (HES); or T-cell–associated HES. (B)
A trial of imatinib is recommended for FIP1L1-PDGFRα-positive CEL or SM patients.
Conventional therapy or a trial of imatinib could be attempted for symptomatic
FIP1L1-PDGFRα-negative patients. FIP1L1-PDGFRα-negative patients who dem-
strate hematologic remissions with imatinib could be placed in a provisional
category of imatinib-responsive (IR), warranting investigation of potential alternative
targets of imatinib in these cases.

abnormal population of T cells. For example, 2 patients in the study
by Cools et al exhibited both the FIP1L1-PDGFRα fusion and clonal cytogenetic abnormalities.3 It is also possible that some
patients with T-cell–mediated HES could have a FIP1L1-PDGFRα
fusion involving both the myeloid and lymphoid lineage. It will be
of particular interest to analyze those patients with T-cell–mediated
HES that progress to T-cell lymphoma or Sézary syndrome.

Treatment
The in vitro and in vivo data reported by Cools et al support the use
of imatinib in FIP1L1-PDGFRα–positive patients.3 Four of 9
patients exhibiting complete hematologic responses to imatinib had
no detectable FIP1L1-PDGFRα gene fusion.3 Therefore, in addition
to conventional therapy, a trial of imatinib could have therapeutic
value in some of these symptomatic FIP1L1-PDGFRα–
negative patients (eg, CEL, unclassified; or HES). The efficacy of
imatinib in a cytokine-driven disease such as T-cell–associated
HES has not yet been reported and requires investigation.

From a broader research perspective, it could also be useful to
 provisionally categorize FIP1L1-PDGFRα–negative patients
with hematologic responses to imatinib as “imatinib-responsive” (IR)
(Figure 4B). Imatinib responsiveness in these patients may be
indicative of clonal molecular abnormalities besides FIP1L1-
PDGFRα. In such cases, an effort should be made to identify
alternate targets of imatinib that contribute to the pathogenesis of
these diseases.

Conclusion
Imatinib’s efficacy in patients with HES and CEL has led to the
identification of FIP1L1-PDGFRαs as a pathogenetically relevant
tyrosine kinase. These findings serve as a platform for new avenues
of research that may translate into improved biologic and clinical
characterization of these eosinophilic diseases. Future investiga-
tions should attempt to address the molecular basis for the response
to imatinib in FIP1L1-PDGFRα–negative patients and how the
constitutively activated FIP1L1-PDGFRα kinase contributes to the
phenotype of hypereosinophilia, similar to oncogenic fusions
involving PDGFRα in a subset of chronic MPDs. It will also be
of interest to evaluate how the expression and function of the fusion
differ between eosinophils and other cell lineages. One means
of addressing this latter question is to study imatinib’s effects on the
proliferation, differentiation, survival, and intracellular signaling
of eosinophils or other enriched myeloid or lymphocyte populations
derived from patients with the FIP1L1-PDGFRα fusion.

Studies are ongoing to further characterize hematologic and
clinical responses among FIP1L1-PDGFRα–positive patients and the
extent to which imatinib can elicit molecular remissions and
cytogenetic responses in individuals with abnormal karyotypes.
Similar to CML, it will be important to evaluate the maximally
effective doses of imatinib needed to achieve these end points
because suboptimal dosing may adversely impact response rates
and the patterns of resistance that emerge.

In their 1994 Blood review, Weller and Bubley indicated that the
goal of therapy for HES patients, particularly those with apparent
chronic nonmalignant disease, should be control of organ damage
rather than simple suppression of asymptomatic eosinophilia.21
This prevailing paradigm will require reappraisal in the subset of
HES patients with FIP1L1-PDGFRα. It will be of great interest to
ascertain whether early treatment of fusion-positive patients with
asymptomatic hypereosinophilia can forestall the development of
organ disease and increase disease-free and overall survival.
Screening of archival specimens for the FIP1L1-PDGFRα fusion
will allow comparison of the natural history of HES in convention-
ally treated patients with those enrolled in future studies evaluating
the efficacy of imatinib. These new biologic and clinical data will
provide a useful framework that clinicians, pathologists, and
molecular biologists can use to develop improved classification
guidelines and algorithms for the diagnosis and treatment of these
eosinophilic disorders.

Acknowledgments
We thank Dr Iwona Wlodarska, Center for Human Genetics,
Leuven, Belgium, for kindly providing the FISH image in Figure 2.
We also gratefully acknowledge collaborating physicians and
investigators for their participation in the clinical and biologic
characterization of patients, Kathleen Dugan and Lenn Fechter for
their assistance in patient care, Rhoda Falkow for tissue banking of
clinical specimens, and patients for their participation in studies of
imatinib in HES. J.G. also recognizes Dr Peter Greenberg for his
valuable mentorship on the NIH K23HL04409 grant.
