Human blood IgM “memory” B cells are circulating splenic marginal zone B cells harboring a prediversified immunoglobulin repertoire

Sandra Weller, Moritz C. Braun, Bruce K. Tan, Andreas Rosenwald, Corinne Cordier, Mary Ellen Conley, Alessandro Plebani, Dinakanta S. Kumararatne, Damien Bonnet, Olivier Tournilhac, Gil Tchernia, Birte Steiniger, Louis M. Staudt, Jean-Laurent Casanova, Claude-Agnès Reynaud, and Jean-Claude Weill

The human peripheral B-cell compartment displays a large population of immunoglobulin M–positive, immunoglobulin D–positive CD27+ (IgM⁺IgD⁺CD27⁺) “memory” B cells carrying a mutated immunoglobulin receptor. By means of phenotypic analysis, complementarity-determining region 3 (CDR3) spectratyping during a T-independent response, and gene-expression profiling of the different blood and splenic B-cell subsets, we show here that blood IgM⁺IgD⁺CD27⁺ cells correspond to circulating splenic marginal zone B cells. Furthermore, analysis of this peripheral subset in healthy children younger than 2 years shows that these B cells develop and mutate their immunoglobulin receptor during ontogeny, prior to their differentiation into T-independent antigen-responsive cells. It is therefore proposed that these IgM⁺IgD⁺CD27⁺ B cells provide the splenic marginal zone with a diversified and protective immune repertoire in charge of the responses against encapsulated bacteria.

Introduction

The human peripheral B-cell compartment displays, in contrast to the mouse, a large population of CD27+ memory B cells that carry a mutated immunoglobulin receptor and represent up to 40% of circulating B cells. These memory B cells include the classical isotype-switched B cells and a population of immunoglobulin M–positive (IgM⁺) B cells, which were originally divided into an IgM-only subset, an IgM⁺IgD+ subset, and a minor IgD-only subpopulation.1-4

The splenic marginal zone (SMZ) is a unique B-cell compartment that contains B cells with a high surface density of IgM and complement receptor 2 (C2 or CD21), and which exhibits a rapid activation and immunoglobulin secretion in response to blood-borne T-independent (TI) antigens.5-7 Human SMZ B cells have been shown to carry somatic mutations, and mutated antibodies can be raised after immunization with T-independent polysaccharidic vaccines.8-11

We hypothesized previously that blood IgM⁺IgD⁺CD27⁺ B cells might form a B-cell subset distinct from the classical germinal-center–derived memory B cells. This proposition was based on the fact that hyper-IgM (HIGM) patients who carry an invalidating mutation of the CD40L gene and do not possess normally developed germinal centers and switched memory B cells12 still presented a subpopulation of circulating IgM⁺IgD⁺CD27⁺ B cells.13,14 These B cells, moreover, carried a mutated immunoglobulin receptor, which led us to suggest that they could represent a different pathway of diversification that did not require a cognate T-B interaction and could thus be involved in T-independent immune responses.14 By means of phenotypic analysis, complementarity-determining region 3 (CDR3) spectratyping during a T-independent vaccination, and gene-expression profiling of the different blood and splenic B-cell subsets, we show here that the blood IgM⁺IgD⁺CD27⁺ B cells indeed correspond to circulating splenic marginal zone B cells in charge of T-independent responses, which is in accordance with a recent report15 and our previous proposition.

Materials and methods

Biologic samples

Fresh spleen samples were obtained from patients undergoing splenectomy owing to spherocytosis. Blood and spleen samples were obtained after

Antibodies

The following antibodies coupled with biotin, fluorescein isothiocyanate (FITC), R-phycocerythrin (PE), allophycocyanin (APC), Cy-Chrome, or the tandem dye PE-cyanin 5.1 (P55) were used for flow cytometry or cell sorting: PC5–anti-CD19 (clone J4.119) and PE–anti-CD27 (clone 1A4–CD27) from Beckman Coulter (Fullerton, CA); APC–anti-CD19 (clone HIB19), Cy-Chrome–anti-CD21 (clone B-Ly4), FITC–anti-CD23 (clone M-T271), PE–anti-CD23 (clone M-L233), and biotin anti-IgD (clone IA6–2) from BD Pharmingen (San Jose, CA); goat antihuman IgD–FITC and biotinylated goat F(ab′)2 anti-human IgM from Caltag (Burlingame, CA). Purified anti-CD1c (clone F10/21A3) was provided by Dr B. Moody (Harvard Medical School, Boston, MA). Biotinylated and purified antibodies were revealed, respectively, with streptavidin PE-Cy7 (PC7) and PE-labeled goat anti-immunoglobulin IgG (Caltag). The following antibodies were used for the histologic studies: anti-CD1c (clone F10/21A3), anti-CD20 (clone L26), and polyclonal rabbit anti-IgD (Dako, Glostrup, Denmark); and anti-CD27 monoclonal antibody (mAb) (137B4) (Novocastra Laboratories; Newcastle, United Kingdom).

Immunohistology

All the antibodies were detected by means of the Vectastain ABC elite kit (Vector Laboratories, Burlingame, CA). The procedure has been described in detail elsewhere. Briefly, serial cryosections of spleen tissue were fixed in cold isopropal for 10 minutes. After blocking of endogenous peroxidase activity by a glucose oxidase method, the sections were incubated overnight at 4°C with the primary antibodies. Bound antibodies were detected by biotinylated goat antirabbit or antimouse IgG (Dako) incubated for 30 minutes at room temperature. The avidin-biotinylated peroxidase complex was prepared according to the manufacturer’s instructions. Sections were incubated with the avidin-biotinylated peroxidase complex for 30 minutes at room temperature. After washing, peroxidase activity was revealed with a tyramide-enhanced ABC method. Sections were visualized by a tyramide-enhanced ABC method. Sections were analyzed by conventional light microscopy. Photographs were made on film with a Zeiss Axiophot photomicroscope using a Plan-Apochromat 10×/0.32 lens. The final magnification before scanning is ×25.

Separation and flow cytometric analysis of IgD⁻CD27⁺ B cells

Human B cells from peripheral blood were enriched by negative selection with the RosetteSep B-cell enrichment cocktail (StemCell Technologies, Vancouver, BC, Canada). Splenic B cells were obtained after Ficoll density centrifugation and enrichment to greater than 98% by means of the Vancouver, BC, Canada). Splenic B cells were obtained after Ficoll density centrifugation and enrichment to greater than 98% by means of the Vancouver, BC, Canada. Human B cells from peripheral blood were enriched by negative selection with a FACS©ilbur with CellQuest software (Becton Dickinson, San Jose, CA). For isolation of splenic or peripheral IgD⁻CD27⁺, IgD⁺CD27⁻, and naive IgD⁻CD27⁻ cells, purified B cells were stained with anti-IgD–FITC, antihuman CD27–PE, and anti-CD19–PC5 and sorted on a FACScan (Becton Dickinson). For microarray analysis, the IgD⁻CD27⁺ and IgD⁺CD27⁻ fractions were submitted to 2 successive sortings. For isolation of peripheral and splenic naive CD27⁻ B cells, CD27⁻ B cells were first removed with the use of CD27–magnetic beads and LD depletion columns (Miltenyi Biotec, Gladbach, Germany). Then, enriched naive B cells were stained and sorted as described. Purity of all samples used for microarray analysis was greater than or equal to 99%.

RNA amplification and cDNA microarray analysis

Total RNA was isolated from sorted splenic and peripheral IgD⁻CD27⁺, IgD⁺CD27⁻, and naive B cells by means of the RNaseasy isolation Kit (Qiagen, Hilden, Germany). RNA samples were amplified in duplicate by means of a standard 2-round linear amplification protocol (Ambion, Austin, TX) to obtain between 25 and 50 μg cRNA. Gene-expression profiling analysis was performed with the use of Lymphochip microarrays. Briefly, amplified cRNA was reverse transcribed, labeled with Cy5, and hybridized to the microarrays together with Cy3-labeled probes generated from a standard pool of RNA derived from 9 lymphoid cell lines.

Amplification and analysis of rearranged V3-23 genes

Genomic DNA was extracted from sorted cells by proteinase K digestion. Rearranged V3-23 gene segments were amplified with Pfu Turbo polymerase (Strategene, La Jolla, CA), with the use of a seminested polymerase chain reaction (PCR) strategy as previously described. PCR products were gel-purified and cloned by means of the TOPO TA Cloning kit (Invitrogen, Carlsbad, CA), and sequences of V3-23–positive colonies were obtained by automated sequencing (ABI310 genetic analyzer; Applera Biosystems, Foster City, CA). The sequences obtained were compared with the germ line V3-23 gene over 288 bp (from Glu1 to Cys92).

H-CDR3 spectratyping

Total RNA from 5 × 10⁶ to 5 × 10⁷ sorted IgD⁻CD27⁺ and naive cells was reverse transcribed by random priming, by means of the ProSTAR First Strand RT-PCR Kit (Strategene). Amplification of V3-15–C₅ transcripts was performed on 2 μL cDNA aliquots with AmpliTaq DNA polymerase (Applera) with the use of a V3-15–specific primer (V3-15 leader: CTGACCTGGATTTTCTTGC) and a primer specific of the C₅ region of the μ heavy chain (μC₅: AAAAGGTGCGGCGGGATGCCAC) (45 seconds at 95°C, 60 seconds at 62°C, 90 seconds at 72°C for 25 cycles). V3-15–C₅ products were subjected to a second round of PCR amplification (45 seconds at 95°C, 60 seconds at 58°C, 90 seconds at 72°C for 25 cycles) with the use of the same μC₅ primer with an internal V3-15–specific framework region 3 (FR3) primer (V3-15–FR3: CACAGCGCTTATTACTGTAC). For H-CDR3 spectratyping, one fifth to one tenth of the purified PCR products were size fractionated on a denaturing 6% polyacrylamide gel and visualized by silver staining (Silver Sequence DNA Staining reagents; Promega, Madison, WI). Individual bands of interest (corresponding to a given CDR3 length) were excised from the gel and crushed in 10 μL water. Reamplification was performed with 1 μL excised PCR product for 20 cycles with the use of the primers and PCR conditions described. Several PCR amplifications were performed from 2 independent cDNAs for each cell sample.

Results

The circulating IgM⁺IgD⁺CD27⁻ B-cell subset displays a splenic marginal zone B-cell phenotype

Mouse and human splenic marginal zone B cells can be distinguished from naive and switched B cells as being IgM⁺IgD⁻CD21⁺CD23⁻. Mouse MZ B cells are CD1d⁺, and it has been proposed that CD1c could be an MZ B-cell marker in humans. When human B cells were analyzed by IgD and CD27 surface markers, they displayed a staining profile similar to the blood with a large compartment of CD27⁺ B cells (about 40%) divided into isotype-switched and IgD⁺ B cells (Figure 1). The CD27⁺IgD⁺ B cells are IgM⁺IgD⁺CD21⁺CD23⁻ and CD1c⁺ as compared with naive B cells, thus displaying the phenotype of splenic marginal zone B cells. Staining of serial sections of a human spleen with CD20, CD27, IgD, and CD1c indeed revealed a stronger expression of CD1c in B cells located in the marginal zone and confirmed the marginal zone localization of IgD⁺CD27⁺ B cells, as previously described.

Similarly to the spleen, blood CD27⁻ B cells are divided into isotype-switched and IgD⁺ B cells. Here again, CD27⁺IgD⁺ B cells are IgM⁺IgD⁺CD21⁺CD23⁻ and CD1c⁺, although the CD21 marker stains the different B-cell subpopulations in this compartment similarly (Figure 1). In most cases, few cells were characterized as IgM-only within the IgD⁺CD27⁺ subset (Figure 1).
IgM-only CD27+ B cells represented 1.1% of blood B cells (a mean value estimated from 11 individuals), with the exception of a 2-year-old child who displayed 7% of IgM-only B cells. Slightly higher values were observed for IgM-only CD27+ B cells in the spleen of children younger than 5 years (a mean value of 2.7%, including a 22-month-old child with 7.5% IgM-only cells).

Immunoglobulin gene mutation frequencies also correlate between splenic and blood compartments, being significantly lower in the IgM-IgD+CD27- subset compared with switched B cells, as previously shown for the blood (Table 1). Remarkably enough, in all IgM+/IgD+/CD27+ B-cell samples analyzed from 1 year on, whether from spleen or blood, more than 90% of V sequences carried somatic mutations, thus indicating that the marginal zone compartment as a whole harbors mutated immunoglobulin genes.

Different types of CD27+ B-cell subsets in CD40- and AID-deficient children

We analyzed 2 other groups of HIGM patients carrying an invalidating mutation either of the CD40 or of the AICDA gene encoding the activation-induced cytidine deaminase (AID). The CD40-deficient patient (40.1) is a 11-year-old child with a homozygous mutation of the CD40 gene described by Ferrari et al.20 This patient shows a peripheral B-cell staining profile similar to CD40 ligand (CD40L)-deficient patients with a large naive compartment and an IgM-IgD+/CD27- B-cell subpopulation (5% of CD19+ cells) as the only “memory” subset (Figure 3). Moreover, these IgM+/IgD+/CD27+ B cells carry a mutated immunoglobulin receptor with a mutation frequency of 3.8% measured on rearranged V3-23 genes: that is, an average of 11 mutations per V_H sequence (Table 2). We also analyzed 2 patients who bear invalidating mutations of the AICDA gene.23,24 One patient (AID.1) presents a homozygous Arg112Cys missense mutation.21 Patient AID.2 presents heterozygous mutations of the AICDA gene (a 1-bp deletion at nucleotide 490 on one allele and an Ala111Thr amino acid missense mutation on the other). In contrast to CD40- and CD40L-deficient patients, AID-deficient patients do have germinal centers but are deficient in the hypermutation and isotype-switch mechanisms.24 Two different CD27+ B-cell subsets are observed in these 2 patients: an IgM+/IgD+ and an IgM-only subset, representing, respectively, 10% to 30% and 5% to 7% of the peripheral B-cell pool (Figure 3). The existence of a clear IgM-only CD27+ subset in AID-deficient patients thus appears to be correlated with the presence of germinal centers. It may represent a stage prior to switching during normal B-cell development, accumulating in AID-deficient patients as a consequence of their defect in the molecular mechanism of isotype switch. The absence of somatic mutations was confirmed for both CD27+ B-cell subsets in these patients (Table 2; also data not shown).

Blood and splenic IgM+/IgD+/CD27+ B cells share a common gene-expression profile

To more extensively compare splenic and blood IgM+/IgD+/CD27+ B cells with splenic and peripheral naive and switched subsets, we used Lymphochip DNA microarrays27 to profile gene expression of these different subsets after purification by cell sorting. We first searched for genes that were expressed at least 2-fold more highly in splenic IgD+/CD27+ populations than in splenic IgD+/CD27- populations with high statistical significance ($P < .005$; $t$ test). Forty-nine genes satisfied these criteria (Figure 4A). We used the hierarchical clustering algorithm to organize the various B-cell populations on the basis of the expression of these genes, and found that the blood IgD+/CD27+ cells clustered with the splenic IgD+/CD27+ in one arm of the dendrogram (Figure 4A). In the other arm of the dendrogram were the splenic and blood IgD-/CD27+ memory B cells and the blood naive B cells. It is important to emphasize that this set of genes was not deliberately selected for similar expression in blood and splenic IgM+/IgD+/CD27+ cells. Therefore, the fact that the hierarchical clustering algorithm grouped these 2 B-cell populations together demonstrates that blood IgM+/IgD+/CD27+ B cells are more related to splenic marginal zone B cells than they are to naive or switched memory B cells. We then searched for genes that were expressed at least 2-fold more highly in the splenic and peripheral IgD+/CD27+ populations than in the IgD-/CD27- populations with high statistical significance ($P < .005$). Figure 4B shows the expression levels in the various B-cell populations of 37 genes that satisfied these selection criteria. This set includes genes that encode the surface markers previously described and associated with marginal zone B cells (IgM, IgD, CD1) as well as a number of genes, like IL-6, not previously associated with this B-cell subpopulation.

*Mut indicates mutation.

*Average mutation frequency. Mutation frequencies were significantly higher in IgD by tissue type (blood, P = .03; spleen, P < 10⁻⁶; nonparametric Wilcoxon score test).

Identical clones are shared by blood and splenic IgM⁺ IgD⁻ CD27⁺ B-cell subsets

To establish a functional link between the splenic and circulating IgM⁺ IgD⁻ CD27⁺ B cells, we studied the evolution of specific VDJ rearrangements by CDR3 spectratyping during a T-independent immunization. A 9-year-old child with a diagnosis of hereditary microspherocytosis, a nonimmunologic disease, was vaccinated against *Streptococcus pneumoniae* and *Neisseria meningitidis* 1 week before undergoing a splenectomy. Blood was collected 1 week before vaccination, 8 days after vaccination at the time of surgery together with the spleen sample, and 5 weeks after vaccination. Rearranged V3-15 genes have been shown to be length, whose representation was increased in the IgM B-cell compartment, whether from blood or spleen, at any stage of contrast, this particular VDJ join could not be found in the naive population, where it was recur -

Healthy and asplenic children younger than 2 years possess a diversified IgM⁺ IgD⁻ CD27⁺ blood B-cell subset

To ask whether hypermutation occurs in the absence of antigenic stimulation is not a feasible task in humans. Children younger than 2 years do not mount proper antibody responses against T-independent antigens such as bacteria carrying polysaccharid capsids like *Haemophilus influenzae* and *S pneumoniae*. This may be due to the immaturity of the SMZ, which is not yet functional because it lacks the appropriate macrophages and/or the retention of the MZ B cells. Therefore, we focused our study on healthy children younger than 2 years of age and also on young and older patients with congenital asplenia.

We have previously shown that the IgM⁺ IgD⁺ CD27⁺ subset appears gradually with age in the circulation of the healthy population, starting at around 1% at birth (cord blood samples) and reaching 7% to 19% at 2 years and a mean of 20% in adults, with large individual variations (7% to 55%). A parallel increase with age was observed for immunoglobulin mutation frequencies with values close to background in cord blood, values that already reach 2% at 1 year and 3% to 4% in adults. For 2 children around 2 years of age, the proportion of IgM⁺ IgD⁺ CD27⁺ B cells in the spleen (20%) and the mutation frequency (about 2%) were similar to values found in older individuals (Table 1; also data not shown).

For asplenia syndromes, we restricted our study to patients whose condition was diagnosed according to several criteria,
including the presence of Howell-Jolly bodies and the absence of spleen by echography, and in some cases by scintigraphy. Some of these patients suffered from frequent pneumococcal infections, and in 2 cases, death of a brother or sister by bacterial sepsis was reported (a detailed description is given in Table 3). Peripherial B cells were analyzed by flow cytometry for 10 patients, ranging from 4 months to 71 years of age, and by immunoglobulin gene mutation frequency for 4 of them (Figure 6C-E). All children with congenital asplenia displayed a normal peripheral CD27+ B-cell compartment with a normal IgM+ IgD+CD27+ B-cell subset. Moreover, in the 4 cases analyzed (14, 18, 23, and 50 months), these IgM+ IgD+CD27+ B cells were heavily mutated with a frequency of 2.2% to 3.7% (Figure 6D). For adult asplenic patients, both IgM+ IgD+ and isotype-switched CD27+ subsets were on average reduced as compared with age-matched controls (Figure 6C; Table 3). Similarly, a reduction of IgM+ IgD+CD27+ B cells appear to represent a minor subset (around 1% on average), which is observed only as a distinct subpopulation in some young children and in some pathologic cases (AID-deficiency and specific autoimmune syndromes; Weller S, unpublished data, 2002). Both of these studies, performed on a large cohort of healthy individuals, appear to contrast with the original description of memory B cells by Klein et al., who described a subpopulation of 10% IgM-only CD27+ B cells in the blood of 3 healthy subjects. Further analysis should help to clarify this issue.

The IgM+ IgD+CD27+ B cells, either in blood or in spleen, display the phenotype of splenic marginal zone B cells, being IgM+ IgD+CD27+CD21+ CD23- CD1c+. A similar observation was made for peripheral B cells in a recent report by Krueztkmann et al. IgM-only CD27+ B cells appear to represent a minor subset (around 1% on average), which is observed only as a distinct subpopulation in some young children and in some pathologic cases (AID-deficiency and specific autoimmune syndromes; Weller S, unpublished data, 2002). Both of these studies, performed on a large cohort of healthy individuals, appear to contrast with the original description of memory B cells by Klein et al., who described a subpopulation of 10% IgM-only CD27+ B cells in the blood of 3 healthy subjects. Further analysis should help to clarify this issue.

The IgM+ IgD+CD27+ B cells, either in blood or in spleen, display the phenotype of splenic marginal zone B cells, being IgM+ IgD+CD27+CD21+CD23-CD1c+ for both organs. Histologic staining of human spleen with CD20, CD27, IgD, and CD1c confirmed that the IgD and CD27 markers indeed identify marginal zone B cells in humans.

When the different splenic and blood B-cell subpopulations are analyzed by gene-expression profiling, the blood and splenic IgM+ IgD+CD27+ B cells appear closer to each other than to any other subset. Some genes seem specifically expressed by these cells such as IL-6, which is also induced after activation of naïve B cells,
Analysis of a CD40-deficient child showed, as for CD40L-deficient patients, an IgM⁺IgD⁺CD27⁺ B-cell subpopulation as the only memory subset. These cells carried a mutated immunoglobulin receptor with an average of 11 mutations per sequence. Such a high mutation frequency, with more than 95% of sequences carrying somatic mutations, was previously observed in CD40L-deficient children. It is clear, however, that this CD27⁺ subset is frequently reduced in HIGM children compared with age-matched controls, as the absence of CD40-CD40L interaction may disturb the cytokine network and alter the development of these cells as previously discussed. This study therefore argues in favor of our previous proposition that circulating IgM⁺IgD⁺CD27⁺ B cells belong to a separate B-cell subpopulation that develops and matures its immunoglobulin receptor outside a germinal center-dependent cognate T-B interaction.

Immunization with a T-independent vaccine followed by splenectomy showed that a specific clone using the V3-15 gene, as followed by its VDJ signature, was strongly and specifically expanded in the splenic and blood marginal zone subsets 1 week after immunization. The same clone could be found 4 weeks after immunization in the blood IgM⁺IgD⁺CD27⁺ cells, although at a lower frequency. These results are consistent with previous reports showing that antibody responses to these bacterial capsular polysaccharides are oligoclonal and mobilize the V3-15 gene. Moreover, the potent amplification of the V3-15 clone in the splenic IgM⁺IgD⁺CD27⁺ population strongly suggests that this clone has been stimulated to expand in the splenic marginal zone by the T-independent vaccine. As previously shown for a similar immunization, responding clones remain for a few weeks in the general circulation. This V3-15 clone carried 8 mutations on its VH gene prior to vaccination. The results showing selection of some additional mutations on this gene suggest that this process could be

ND indicates not determined.
*One asplenic brother died from invasive infection (Streptococcus spp).
‡Or Ivemark syndrome (visceral heterotaxia: right atrial isomerism, cardiac malformation and asplenia).
§Not visualized by ⁹⁹ᵐTc sulfur colloid scintigraphy.
¶Germ not identified.

Figure 5. B-cell clones with an identical V3-15 CDR3 shared by IgM⁺IgD⁺CD27⁺ B cells from blood and spleen during a T-independent response. Amplification of V3-15-C, mRNA sequences was performed from naive and IgM⁺IgD⁺CD27⁺ B cells of a 9-year-old child undergoing splenectomy and immunized against S. pneumoniae and N meningitidis (plain polysaccharidic vaccines). The following samples were analyzed: blood before immunization, blood at the time of splenectomy (ie, 8 days after immunization), spleen, and blood 5 weeks after immunization. The first V3-15–specific PCR products were further amplified with V3-15–specific FR3 and Cγ2 primers, and the resulting products fractionated by denaturing gel electrophoresis. A specific CDR3 size was excised from the gel after silver staining and reamplified with specific primers, and the resulting products fractionated by denaturing gel electrophoresis. A specific CDR3 size was excised from the gel after silver staining and reamplified with the same FR3 and Cγ2 primers, and sequences were determined after cloning. Several PCR amplifications were performed from 2 independent cDNAs for each cell sample. The recurrent CDR3s encompassing the V3-15 and Jα3 junctions observed in the various IgM⁺IgD⁺CD27⁺ fractions are shown, with the most frequently occurring sequence taken as reference (CDR3 is defined as amino acids included between the conserved Cys residue of FR3 and Trp residue of Jα3 segments). *Clones found repeatedly in independent PCR amplifications.
reactivated in the spleen during the week following immunization. Moreover, they unambiguously establish that IgM⁺IgD⁺CD27⁺ B cells do recirculate between blood and splenic marginal zone in humans.

We have previously reported that the circulating IgM⁺IgD⁺CD27⁺ B-cell population was, surprisingly, already well developed and mutated at 1 year of age in healthy children, a stage at which the splenic marginal zone is not yet functional. In children younger than 2 years, the response to Ti antigens has been reported to be defective, with a high incidence of infections caused by encapsulated bacteria. Our results on young children are thus intriguing since they indicate that circulating IgM⁺IgD⁺CD27⁺ B cells can develop and diversify their immunoglobulin receptors during ontogeny before a functional splenic marginal zone is matured. It is then tempting to propose that these cells could at this early stage have diversified their immunoglobulin receptors by hypermutation as a developmental program rather than following an immune response. Such a possibility has been mentioned in the original work describing these cells. A program of diversification involving the hypermutation process to generate a preimmune repertoire has already been reported for species such as sheep and rabbits, and humans could have conserved this strategy for one arm of their B-cell system. Hypermutation as a means to enlarge the preimmune repertoire has been recently proposed for the mouse as well, but such a process seems to occur only in specific models harboring a highly restricted V gene usage. It is clear that in all these models, a window of tolerance is likely to accompany this prediversification step.

When looking at adult asplenic patients, we could detect a clear diminution of CD27⁺ B cells, including both the isotype-switched and the IgM⁺IgD⁺CD27⁺ B cells, in accordance with Krutzen et al, and suggesting, as proposed by these authors, that the spleen could be the main source of these cells. Surprisingly, however, the younger asplenic patients we analyzed did not show, as opposed to their results, any significant alteration in the number and mutational status of their IgM⁺IgD⁺CD27⁺ B cells, implying that there may be large variations among these younger patients. The presence of these cells in several asplenic children would nevertheless suggest that other sites, such as marginal zone-like regions of Peyer patches and tonsils, might substitute for the developmental function of the spleen, without being able to sustain a similar B-cell production in adulthood or to replace the role that the splenic environment plays in supporting T-independent responses.

Immune responses to Ti antigens are known to generate neither a memory response nor a maturation of affinity and to give protection for approximately 6 months. Effectively, SMZ B cells can switch after activation and differentiate rapidly into plasma cells that can probably remain in the organism for a few months. In such a sense, in spite of their previous characterization on the basis of their mutated immunoglobulin genes, IgM⁺IgD⁺CD27⁺ B cells would represent an immediate line of defense with none of the functional characteristics of memory. It has in fact been proposed that natural antibodies, which are essential for the immediate protection they provide against an infection, are constantly secreted by bystander stimulation of memory IgM and switched B cells. Most of the natural mutated IgM antibodies present in human serum are thus probably produced, as previously proposed, by circulating and splenic IgM⁺IgD⁺CD27⁺ B cells.

In conclusion, in this work and the previous ones by our group and by Krutzen et al, a new scheme of human B-cell development seems to emerge in which the IgM⁺IgD⁺CD27⁺ B cells in charge of T-independent responses follow a separate pathway of differentiation as compared with the classical B cells involved in T-dependent responses. We would also suggest that immunoglobulin gene hypermutation may play a double task in the human B-cell repertoire, by allowing the improvement of low-affinity antibodies during classical T-dependent immune responses, but also by generating a protective and diversified marginal zone B-cell repertoire that can be mobilized in rapid T-independent antibacterial responses.

Acknowledgments

We thank Ninon Lesage and Kun Yang for their contribution. We thank also Jérôme Mégret and Frédéric Delbos for cell sorting. We thank Dr B. Moody for the gift of the anti-CD1c antibody, Dr V. Minard for the clinical follow-up of asplenic patients, and Prof C. Rose for providing blood sample. We thank Dr A. Alcais for the statistical analysis. Many thanks to Capucine Picard and Claire Fieschi for their invaluable support. The authors are grateful to Benedita Rocha for critical reading of the manuscript.
