Platelet P-selectin is required for pulmonary eosinophil and lymphocyte recruitment in a murine model of allergic inflammation

Simon C. Pitchford, Stefania Momi, Silvia Giannini, Lucio Casali, Domenico Spina, Clive P. Page, and Paolo Gresele

Platelets are necessary for lung leukocyte recruitment in a murine model of allergic inflammation, and platelet–leukocyte aggregates are formed in circulating blood of patients with asthma after allergen exposure. However, it is unknown how platelets induce pulmonary leukocyte recruitment in asthma. Here, we have investigated the importance of platelet adhesion molecule expression on pulmonary eosinophil and lymphocyte recruitment and on leukocyte CD11b and very late antigen (VLA)–4 expression in mice. Pulmonary leukocyte recruitment in platelet-depleted mice (sensitized and exposed to ovalbumin) transfused with fixed, unstimulated platelets (FUSPs) was abolished, whereas transfusion with platelets stimulated and fixed (FSPs), expressing P-selectin and P-selectin glycoprotein ligand-1 (PSGL-1), restored eosinophil and lymphocyte recruitment. Transfusion with platelets from P-selectin–deficient mice, or with FSPs stimulated in the presence of a blocking anti–P-selectin antibody, were unable to restore pulmonary leukocyte recruitment. Flow cytometric analysis revealed increased expression of CD11b and VLA-4 on leukocytes attached to platelets after allergen exposure, and CD11b expression on leukocytes was suppressed in thrombocytopenic mice but was restored with the transfusion of FSPs, but not FUSPs, a phenomenon concurrent with the formation of platelet–leukocyte complexes. P-selectin expression on the surfaces of platelets is a major requirement for pulmonary eosinophil and lymphocyte recruitment, allowing circulating platelets to bind to and stimulate leukocytes for endothelial attachment. Introduction

Bronchial asthma has been recognized as a chronic inflammatory disease associated with leukocyte infiltration and airway epithelial damage. It is now clear that eosinophil, neutrophil, mast cell, and T-lymphocyte activation occurs in allergic asthma, whereas platelets appear to be important in murine models of chronic allergic inflammation. The presence of intravascular platelet aggregates within bronchial biopsy specimens in patients with asthma has also been reported. Substantial clinical evidence demonstrates intravascular platelet activation accompanying allergen-induced bronchocstriction in patients with asthma, suggestive of participation of these blood elements in the pathophysiology of asthma, and the expression of P-selectin on platelets was found to be increased in patients with asthma. This is also apparent in other diseases with a substantial inflammatory component, including atherosclerosis, and in tumor metastasis, a disease process with many similarities to leukocyte recruitment. The implication being that platelet activation is a general feature of diseases in which leukocyte recruitment from the circulation to particular anatomic sites is required.

Using immune and nonimmune methods of platelet depletion to render mice severely thrombocytopenic, we recently demonstrated in a murine model of allergic inflammation that platelets are essential for eosinophil and lymphocyte recruitment to the lungs. This phenomenon was dependent on the presence of intact platelets rather than on the release of any soluble, platelet-released, proinflammatory mediators. Although our studies were conducted investigating eosinophil and lymphocyte recruitment, it can be envisaged that leukocyte recruitment from the circulation in general can be facilitated by a platelet-dependent mechanism and not restricted to the cells thus far studied given that the recruitment of other cell types is also dependent on platelets, as reported during atherosclerotic lesion formation.

Interestingly, in our own studies, there was a significant increase in circulating platelet–leukocyte complexes upon allergen exposure in mice sensitized to allergen-allergen exposure. Leukocytes attached to platelets displayed a significant increase in the expression of the adhesion molecule CD11b, implying that platelets contribute to leukocyte activation and prime leukocytes for tissue recruitment. This finding was mirrored in patients with asthma undergoing allergen challenge.

It is likely, therefore, that the requirement for platelets in inducing leukocyte recruitment to extravascular tissues during allergic lung inflammation occurs at the level of contact-dependent signaling to leukocytes, initiating the expression of adhesion molecules required for the attachment to activated endothelium. Indeed, P-selectin expression on platelets, but not on endothelial cells, has been shown to be responsible for leukocyte rolling along endothelium. Platelets roll on stimulated endothelium in vivo in a manner similar to that of leukocytes, suggesting that platelets may act as a bridge upon which leukocytes adhere to the endothelium from the circulation. Similarly, platelets have been shown to facilitate eosinophil–endothelial adherence when taken from allergic patients with asthma but not from healthy subjects.

Although it is unknown at which point of the adhesion process platelets become involved in the murine model of allergic inflammation described, in other models the occurrence of platelet–leukocyte complexes is abolished by the administration of antibodies to P-selectin or to its counter ligand, P-selectin glycoprotein ligand-1 (PSGL-1). Mice made selectively deficient in L- or P-selectin exhibited virtually no leukocyte rolling, suggesting that platelets may “prime” leukocytes for efficient endothelial trafficking at the level of the circulation.

In the present study, we have investigated the importance of surface-expressed mediators on activated platelets for eosinophil and lymphocyte recruitment and platelet–leukocyte complex formation in a murine model of allergic inflammation, specifically the requirement for surface-expressed P-selectin on platelets. We have also recorded the increased occurrence of platelet–leukocyte complexes in the circulating blood of allergen-challenged mice and have linked this to an increased expression of very late antigen (VLA)-4 and CD11b on the surface of leukocytes.

Materials and methods
Sensitization of mice to ovalbumin
Male C57BL/6 mice (each weighing 20-25 g; Charles River) were immunized with chicken egg ovalbumin (OVA; 10 μg/0.4 mL intraperitoneally) on days 0 and 7, as previously described. Mice were subsequently sensitized on days 15, 16, and 17 (model 104; Faset Aerosol Prisma; particle size 2-5 μm). Twenty-four hours after the last allergen challenge, mice were studied as outlined in this article. In some studies, blood was taken 24 hours after the start of challenge on day 15, the first day of challenge, for flow cytometric analysis. Local ethics committee approval was obtained from the University of Perugia.

Busulfan-induced platelet depletions
Busulfan (Sigma-Aldrich, Poole, United Kingdom), a bone marrow suppressor cell–specific depressing agent, was used to deplete platelets, as previously described. Busulfan was prepared in polyethylene glycol 400 (25 mg/mL) and was heated at 65°C to 70°C until the mixture went into solution, before dilution (1:8) in warm saline for injection on days –4, –2, and 1 of the immunization protocol (20 mg/kg, 0.2 mL administered intraperitoneally).

Ex vivo manipulation of platelets and restoration of platelet population in thrombocytopenic mice
Citrated blood was taken from OVA-immunized mice and centrifuged for 20 seconds using an Eppipette. The result platelet-rich plasma (PRP) was gel filtered with Sepharose 2B in Tyrode buffer. Gel-filtered platelets were diluted to 1 × 10^8 platelets per microliter and were stimulated for 4 minutes with 1 U/mL bovine thrombin (Sigma-Aldrich) in the presence of RGD peptide (1 mM) and CaCl2 (4 mM). The reaction was stopped with hirudin (1 U/mL). Platelet suspension was then fixed for 10 minutes with an equal volume of 2% paraformaldehyde (PFA) and was centrifuged at 1000 g. The pellet was resuspended in phosphate-buffered saline (PBS) supplemented with PGI2 (0.02 μM). These fixed stimulated platelets (FSPs) were then intravenously injected into mice made thrombocytopenic by busulfan treatment. In other experiments, washed platelets were fixed without previous stimulation with thrombin (fixed unstimulated platelets [FUSPs]).

Thrombocytopenic mice received 2 transfusions of platelets, 20 minutes before allergen challenge, on the first 2 days of exposure. In some experiments, platelets were stimulated with thrombin in the presence of 100 μg monoclonal anti–P-selectin blocking antibody (RB40.34; Becton Dickinson, San Diego, CA) before reinjection. Typically, the injection volume of 0.2 mL contained 1.0 to 1.5 × 10^8 platelets, giving a cumulative dose of 2.0 to 3.0 × 10^8 platelets over the 2 injections. Preliminary studies were conducted with the administration of varying doses of antiplatelet antisera (APAS) into OVA-immunized mice, which produced different degrees of thrombocytopenia. This allowed us to determine the threshold concentration of circulating platelets that was expected to affect pulmonary leukocyte recruitment after reinfusion. After stimulation, the expression of P-selectin and PSGL-1 on the surfaces of platelets was quantified using flow cytometry, as explained below.

In studies using P-selectin–deficient mice, washed platelets from wild-type (C57Bl6/J) and P-selectin–deficient mice (C57Bl6/J129Swj background; Jackson Laboratory, Bar Harbor, ME) were prepared as described. Platelets were injected intravenously into thrombocytopenic mice 20 minutes before allergen challenge on the first 2 days of exposure. Typically, the injection volume of 0.2 mL contained 2.5 to 3.0 × 10^8 platelets, giving a cumulative dose of 5.6 to 6.0 × 10^8 platelets over the 2 injections.

Bronchoalveolar lavage
Twenty-four hours after the last aerosol challenge on day 17, mice were anesthetized with sodium pentobarbital (0.1 mL 5% solution intraperitoneally), the trachea was exposed and cannulated, and 3 aliquots (0.5 mL) each of warm, sterile saline solution were injected into the lung; the resultant fluid was drawn out with a 1-mL syringe and put on ice. Total and differential cell counts were performed in a Burker chamber with a 25 × objective.

Platelet and leukocyte counts in blood and bone marrow
Blood (5 μL) was collected before challenge by tail bleed, using a pipette. The blood was added to 95 μL Stromatol solution (Mascia Brunelli srl, Milan, Italy) for platelet counting using a Burker chamber (Neuroprobe Inc, Gaithersburg, MD) under a 40 × objective. Total and differential blood cell counts were performed as previously described. Bone marrow was retrieved from both femurs taken from the hindlimbs of mice, and cytopsins were prepared from leukocytes resuspended in 1 mL saline. Total and differential cell counts were then enumerated.

Lung histology
Some mice were killed 30 hours after the last allergen exposure; lungs were removed, processed with OCT compound (TissueTek, Redding, CA), and frozen at –80°C for immunofluorescence staining. Eosinophils were identified by morphologic characteristics and with a primary rat antimouse major basic protein (MBP) antibody (MT2-14.7.2; a kind gift from Dr J. Lee, Mayo Clinic, Scottsville, AZ) and an antirat immunoglobulin G–fluorescein isothiocyanate (IgG-FITC)–labeled secondary antibody. Platelets were identified with a primary goat anti-CD41 antibody (sc-6604; Santa Cruz Biotechnology, Santa Cruz, CA) and an antirat IgG–cyanin 3 (Cy3)–labeled secondary antibody. Slides were observed under a 100 × objective using a fluorescence microscope.

Flow cytometry
Blood was obtained by means of cardiac puncture from anesthetized mice on citrate 24 hours after the first day of aerosol challenge and was analyzed for the presence of platelet–leukocyte aggregates and for CD11b and VLA-4 on leukocytes. Monoclonal antibodies, used in saturating concentrations, were FITC-labeled anti-CD41 (gpIb-IIIb no. 553848), phycocerythrin (PE)–labeled anti-CD11b (Mac-1 no. 557397), and streptavidin-labeled anti-CD49d (VLA-4 no. 557406, with second-step conjugation to streptavidin–PE conjugate no. 554061) (all from PharMingen, San Diego, CA) or control antibodies. After a 10-minute incubation at room temperature in the dark, 450 μL water was added to lyse red blood cells for a further 10 minutes before 500 μL paraformaldehyde (1% in PBS) was added. Samples were read within 4 to 6 hours on a FACScan flow cytometer (Coulter Epics XL-MCL Instrumentation, Milan, Italy). Live gating was performed on leukocyte-sized events to exclude single platelets; leukocytes were identified by their forward and side scatter characteristics. Events in this region,
which were positive for CD41, were considered to represent platelet–leukocyte aggregates. CD11b- and VLA-4–positive events on platelet–leukocyte complexes were then identified from this region. CD11b- and VLA-4–positive events on leukocytes in general were identified by positive gating for PE fluorescence, and leukocytes not attached to platelets were identified as excluded from a gate ascertaining FITC-positive events.

In some experiments, the percentage of platelets positive for P-selectin and PSGL-1 expression was obtained from washed platelet samples that were then reinfused into platelet-depleted animals. Platelets were positively identified by the CD41-FITC or the CD61-PE (integrin β3 chain no. 553347) antigen, and the surface expression of P-selectin and PSGL-1 was identified using antibodies against CD62P-FITC (P-selectin no. 553744) or CD154-PE (PSGL-1 no. 555306).

**Statistical analysis of data**

Data are expressed as mean ± SEM. Bronchoalveolar (BAL) fluid leukocyte numbers, blood leukocyte and platelet numbers, and FACScan data were analyzed using one-way analysis of variance (ANOVA), followed by Bonferroni multiple-comparisons test. Nonlinear regression (1-site competition) was performed for data studying the effects of APAS on eosinophil recruitment for calculation of the coefficient of correlation (r²). All analyses were conducted using the GraphPad Prism statistical package (version 4.0; Graph Pad, San Diego, CA). P less than .05 was considered significant.

**Results**

**Effects of activated platelet surface mediator expression on pulmonary eosinophil and lymphocyte recruitment**

Allergen sensitization and subsequent allergen exposure by aerosol resulted in a significant recruitment of eosinophils to the lungs 24 hours after the last allergen challenge compared with sham-sensitized animals (8.1 ± 2.2 × 10⁵ cells/mL vs 0.1 ± 0.1 × 10⁵ cells/mL; P < .001). Mice rendered severely thrombocytopenic with busulfan (0.1 ± 0.1 × 10⁹ cells/mL vs 1.1 ± 0.1 × 10⁹ cells/mL; 91% depletion; P < .001) before the start of allergen exposure showed significantly reduced recruitment of eosinophils to the lungs 24 hours after the last allergen challenge (1.0 ± 0.3 × 10⁵ cells/mL; P < .01) (Figure 1A). This phenomenon was also observed at an earlier time, 8 hours after allergen challenge (OVA control, 1.7 ± 0.4 × 10⁵ cells/mL; OVA + busulfan, 0.3 ± 0.1 × 10⁵ cells/mL; P < .01). Busulfan treatment only marginally affected total circulating leukocytes (1.1 ± 0.1 × 10⁶ cells/mL vs 0.83 ± 0.01 × 10⁶ cells/mL, 24% depletion; P < .05), but it did not significantly reduce circulating blood eosinophil levels (OVA controls, 3.8 ± 0.8 × 10⁵ cells/mL; OVA + busulfan, 3.9 ± 0.9 × 10⁵ cells/mL) or eosinophil levels in the bone marrow (OVA controls, 2.3 ± 0.6 × 10⁵ cells/mouse; OVA + busulfan, 2.2 ± 0.2 × 10⁵ cells/mouse). Furthermore, the infusion of gel-filtered platelets (containing no leukocytes) from donor animals into thrombocytopenic mice significantly restored pulmonary eosinophil recruitment into the lung, as measured in BAL fluid, compared with busulfan-treated controls (5.8 ± 1.6 × 10⁵ cells/mL vs 1.0 ± 0.03 × 10⁵ cells/mL; P < .01) to a level not significantly different than that of OVA controls (Figure 1A).

Inhibition of eosinophil recruitment in mice administered APAS occurred when platelet depletion exceeded 83% compared with the normal value (dose-response curve; 50% effect (EC₅₀) = 85.8%; r² = 0.9606; n = 19) (Figure 1A, inset). For this reason, mice depleted of platelets by more than 90% were used in this study, and subsequent procedures investigating the effect of platelet reconstitution on lung leukocyte recruitment were conducted with a dose of platelets that increased circulating numbers to at least 25% to 40% of original values.

In contrast, eosinophil recruitment was not restored in thrombocytopenic mice transfused with gel-filtered resting platelets that were fixed with 1% PFA before transfusion (FUSPs) (0.3 ± 0.1 × 10⁶ cells/mL vs 1.0 ± 0.03 × 10⁶ cells/mL in thrombocytopenic control mice) (Figure 1A). However, the infusion of gel-filtered platelets that had been stimulated with thrombin and then fixed with 1% PFA (FSPPs) significantly restored eosinophilia (5.2 ± 0.9 × 10⁶ cells/mL; P < .05) to levels comparable to those observed in the BAL fluid of OVA-sensitized mice with normal platelet counts (8.1 ± 2.2 × 10⁵ cells/mL) (Figure 1A). Interestingly, there was a significant difference in the percentage of platelets expressing the adhesion molecules P-selectin and PSGL-1 on the surface of FSPPs compared with FUSPs, as measured by flow cytometry (P-selectin: FSP, 55.6% ± 11.5%; FUSP, 25.9% ± 7.6%; P < 0.05) (PSGL-1: FSP, 24.8% ± 4.7%; FUSP, 7.8% ± 1.8%; P < .01). Levels of P-selectin and PSGL-1 on FSPPs were found to be equivalent to levels found on washed platelets (WPs) (P-selectin: 20.3% ± 4.8%; PSGL-1: 6.7% ± 3.0%).

Similarly, platelet depletion significantly reduced pulmonary lymphocyte recruitment compared with OVA-sensitized controls (P < .05) (Figure 1B), and the transfusion of WPs and FSPPs restored lymphocyte recruitment in platelet-depleted mice whereas the transfusion of FUSPs did not (Figure 1B). Busulfan administration did not significantly reduce lymphocyte levels in femur.
bone marrow compared with OVA-sensitized control mice (4.1 ± 0.6 × 10⁶ cells/mouse vs 3.3 ± 0.7 × 10⁶ cells/mouse).

Further studies were conducted to specifically investigate the role of platelet P-selectin on pulmonary eosinophil recruitment with the use of washed platelets taken from P-selectin-deficient mice, cross-transfused into OVA-sensitized thrombocytopenic mice. Eosinophil recruitment remained suppressed in thrombocytopenic mice receiving washed platelets deficient in P-selectin (1.3 ± 0.4 × 10⁷ cells/mL) compared with thrombocytopenic control mice (1.6 ± 0.4 × 10⁷ cells/mL) (Figure 2A). On the contrary, the transfusion of washed platelets taken from normal C57BL/6 mice restored eosinophil recruitment. This was significantly different than in mice receiving P-selectin-deficient platelets (3.5 ± 0.3 × 10⁷ cells/mL vs 1.3 ± 0.4 × 10⁷ cells/mL; P < .05) but was not significantly different than in OVA-immunized controls (6.1 ± 1.5 × 10⁷ cells/mL) (Figure 2A). Additionally, in this set of experiments, busulfan administration to OVA-sensitized mice significantly suppressed circulating blood platelet numbers compared with OVA-sensitized control mice (0.06 ± 0.01 × 10⁹ cells/mL vs 0.84 ± 0.01 × 10⁹ cells/mL; 93% depletion; P < .001), but it did not significantly affect leukocyte numbers (0.78 ± 0.1 × 10⁶ cells/mL vs 0.85 ± 0.1 × 10⁶ cells/mL; 8% depletion; P = NS).

In another set of experiments, after co-incubating platelets with a blocking antimag P-selectin antibody or with an aspecific IgG, we investigated the effects of transfusing fixed, thrombin-stimulated platelets into thrombocytopenic mice on eosinophil recruitment. Platelets incubated with a control IgG before thrombin stimulation displayed a significant increase in P-selectin expression compared with nonstimulated platelets, as measured by flow cytometry (17.0% ± 2.2% vs 5.9% ± 0.2%; P < .05). Incubation with the blocking anti–P-selectin antibody suppressed the percentage of platelets positive for P-selectin fluorescence (7.9% ± 2.8%). The infusion of fixed platelets prestimulated in the presence of an anti–P-selectin antibody did not restore recruitment of eosinophils to the lungs compared with control thrombocytopenic mice (0.4% ± 0.2% × 10⁷ cells/mL vs 0.5% ± 0.2% × 10⁷ cells/mL). However, in thrombocytopenic mice transfused with platelets stimulated in the presence of control IgG, pulmonary eosinophil recruitment was significantly restored (1.5 ± 0.3 × 10⁷ cells/mL; P < .05 compared with mice transfused with FSP + anti–P-selectin) and was not significantly different from OVA-immunized control mice (2.2 ± 0.6 × 10⁷ cells/mL) (Figure 2B).

To exclude enhanced platelet clearance as a cause of the lack of effect of ex vivo anti–P-selectin–treated platelets in restoring eosinophil lung recruitment, control experiments were performed. Platelet numbers increased 1 hour after reinfusion (platelet dose, 1.6 ± 10⁸ cells per mouse) of FSPs (0 hour, 1.7 ± 0.2 × 10⁸ cells/mL; 1 hour, 2.9 ± 0.1 × 10⁸ cells/mL); fixed platelets incubated with a control IgG antibody (FSP + IgG) (0 hour, 1.6 ± 0.3 × 10⁷ cells/mL; 1 hour, 2.7 ± 0.3 × 10⁷ cells/mL); control experiments were performed. Platelet depletion obviously led to a significant decrease in the percentage of leukocytes attached to platelets after allergen exposure compared with that in OVA-sensitized controls (1.5 ± 0.3 × 10⁷ cells/mL; 1 hour, 2.9 ± 0.1 × 10⁷ cells/mL; 0.4% ± 0.2% × 10⁷ cells/mL vs 0.5% ± 0.2% × 10⁷ cells/mL).

Histologic analysis of lung tissue, after the first day of allergen exposure, revealed the presence of platelets (red, positive for CD41) attached to eosinophils (green, positive for MBP) and multilobed nuclei migrating to lung tissue (Figure 3A-C). Studies were thus performed to examine the presence of platelet–leukocyte complexes in circulating blood 24 hours after the initial day of allergen exposure. This time was chosen because preliminary studies have shown it to be optimal for blood eosinophilia after allergen exposure. Flow cytometric analysis of whole blood revealed a significant increase in the percentage of leukocytes positive for the platelet-specific marker CD41 in blood taken from OVA-sensitized mice compared with sham-sensitized controls (measured in relation to basal: 136.1% ± 2.9% vs 100.0% ± 2.9%; P < .05). Although platelet depletion obviously led to a significant decrease in the percentage of leukocytes attached to platelets after allergen exposure compared with that in OVA-sensitized controls (43.6% ± 8.1%; P < .001), thrombocytopenic mice transfused with FSPs displayed a significant increase in the percentage of
leukocytes complexed to platelets than did mice receiving FUSPs (measured in relation to basal, \(92.6\% \pm 19.5\%\) vs \(33.1\% \pm 7.8\%\); \(P < .05\)) (Figure 4), demonstrating the ability of FSPs to attach to circulating leukocytes after reinfusion in thrombocytopenic mice, in correlation to the increased expression of the adhesion molecules P-selectin (\(P < .05\)) and PSGL-1 (\(P < .05\)) on the surface of FSPs (P-selectin, 54.4% \pm 8.2%; PSGL-1, 35.8% \pm 8.1%) compared with the surface of FUSPs (P-selectin, 18.8% \pm 7.4%; PSGL-1, 10.5% \pm 0.6%). In this set of experiments, busulfan administration to OVA-sensitized mice significantly suppressed circulating blood platelet numbers compared with those in control mice (0.07 \pm 0.01 \times 10^9 cells/mL vs 1.05 \pm 0.06 \times 10^9 cells/mL; 93% depletion; \(P < .001\)).

**Effects of platelets on the expression of adhesion molecules on the surface of circulating leukocytes**

VLA-4 expression on circulating leukocytes was not different between sham and OVA-sensitized mice after allergen exposure (Figure 5A), though in mice depleted of platelets there was a tendency to increase in VLA-4 expression on leukocytes expressing CD11b was significantly suppressed compared with the percentage in OVA-sensitized control mice \((59.5\% \pm 13.0\%; P < .001)\) (Figure 6A). The reinfusion of FUSPs had no effect on the percentage of leukocytes expressing CD11b \((39.5\% \pm 11.6\%; P < .001)\), though there was a significant increase in the percentage of leukocytes expressing CD11b in mice administered FSPs (93.2% \pm 33.4%; \(P < .05\)) (Figure 6A).

An analysis of leukocytes attached to platelets also revealed a significant increase in the percentage of leukocytes expressing CD11b in OVA-sensitized mice compared with sham-sensitized controls \((145.2\% \pm 19.0\%\) vs \(102.8\% \pm 10.6\%; \(P < .05\)) (Figure 6B). Furthermore, the reinfusion of FSPs into thrombocytopenic mice increased the percentage of leukocytes complexed to platelets expressing CD11b \((64.1\% \pm 22.9\%)\) compared with mice receiving FUSPs \((15.6\% \pm 4.9\%; P < .05)\). On the contrary, there was no difference in the percentage of non–platelet-bound leukocytes expressing CD11b between sham- and OVA-sensitized mice, and this percentage remained unaffected in thrombocytopenic mice (Figure 6C).

**Discussion**

We have recently demonstrated, in a murine model of allergic inflammation using immune (antiplatelet antiserum) and nonimmune (busulfan) platelet depletion, that platelets are essential for eosinophil and lymphocyte recruitment to the lungs.\(^8\) This phenomenon depends on the presence of intact platelets rather than on the release of any soluble, proinflammatory mediators from platelets during periods of allergen exposure.\(^8\) In the present study, we provide evidence that pulmonary eosinophil and lymphocyte recruitment in a murine model of allergic inflammation is dependent on leukocyte contact with activated platelets expressing adhesion molecules on their surface and that platelet P-selectin is of major importance in these events. Thus, platelet attachment to leukocytes by platelet P-selectin or its ligand, PSGL-1, increases the expression of adhesion molecules on the surface of leukocytes, priming them for diapedesis through vessel walls.

Primarily, pulmonary eosinophil and lymphocyte recruitment, which was significantly suppressed in mice depleted of platelets, was restored by the transfusion of ex vivo thrombin–stimulated and

![Figure 3. Identification of platelet–eosinophil complexes in lungs taken from allergen-sensitized mice after allergen exposure.](image_url)

![Figure 4. Circulating platelet–leukocyte complexes are increased in allergen-sensitized mice after allergen exposure.](image_url)
then fixed platelets (FSPs). This did not occur in mice receiving unstimulated fixed platelets (FUSPs). FSPs were found to display increased levels of the adhesion molecules P-selectin and PSGL-1 on their surface compared with FUSPs; levels in the latter did not differ from those of resting washed platelets. The expression of P-selectin and PSGL-1 on FUSPs, though still higher than levels found normally on platelets circulating in blood, is higher than the expression found on FSPs. The lack of eosinophil-recruiting activity of FUSPs may, therefore, reflect a threshold effect by which a critical amount of adhesive molecules must be present on the platelet surface before leukocyte activation is affected. The threshold value of platelet depletion required to suppress eosinophil recruitment in sensitized animals supports this conclusion. A role for platelet P-selectin in eosinophil and lymphocyte recruitment was demonstrated because gel-filtered platelets obtained from P-selectin–deficient mice and transfused into thrombocytopenic mice did not restore pulmonary eosinophil and lymphocyte recruitment. This evidence suggests that platelet-derived P-selectin is important for eosinophil and lymphocyte recruitment, whereas endothelial-derived P-selectin plays a secondary role in leukocyte recruitment because the thrombocytopenic recipient mice were not deficient in P-selectin. The role of platelet-expressed P-selectin was confirmed in experiments performed with FSPs stimulated in the presence of an antismouse P-selectin monoclonal antibody.

The relevance of P-selectin in eosinophil and lymphocyte diapedesis and, therefore, in allergic inflammation has been previously demonstrated in a murine model similar to ours. However, the role of platelet P-selectin was not investigated, though it has since been reported that platelet P-selectin, but not endothelial P-selectin, is critical for neutrophil recruitment into the outer and inner medulla of the kidneys in a murine model of acute postischemic renal failure and in atherosclerotic lesion development. Furthermore, the recent demonstration that circulating leukocyte/monocyte aggregates promote the formation of atherosclerotic lesions suggests that circulating activated platelets are a necessary facet of the inflammatory response, perhaps through the platelet P-selectin–mediated delivery of platelet-derived proinflammatory factors to leukocytes and the vessel wall. Interestingly, platelets have been shown to facilitate eosinophil–endothelial adherence when taken from patients with asthma but not from healthy subjects, and this depended on activated platelets expressing P-selectin.

Previous studies using in vivo models of inflammatory reactions in the skin and the peritoneal cavity have demonstrated that P-selectin may play an important role in allergic inflammation earlier (3–12 hours) rather than later (20–24 hours) after allergen challenge. We observed the suppression of leukocyte recruitment to the lungs by platelet depletion at both early (8 hours) and late time points (24 hours) after allergen challenge and, therefore, do not confirm such a time-dependent phenomenon in our model. Indeed, others studying allergic inflammation in the lung also demonstrated the importance of P-selectin at later time points (24 hours) after allergen challenge.

In this study, we have attempted to investigate the mechanism through which stimulated, circulating platelets activate leukocytes and prime them for the subsequent steps of initial vessel wall trafficking through the up-regulation of adhesion molecules. Here, we found that the formation of circulating platelet–leukocyte complexes is significantly increased in allergen-sensitized mice compared with sham-sensitized controls after allergen exposure.
and that the percentage of leukocytes attached to platelets expressing both CD11b and VLA-4 is increased. This phenomenon was not seen with circulating FUSPs, whereas the formation of circulating platelet–leukocyte complexes expressing CD11b and VLA-4 was restored with the infusion of FSPs. The percentage of leukocytes not attached to platelets and expressing VLA-4 or CD11b did not differ between sham- and allergen-sensitized mice, implying that platelet–leukocyte complexes are further required for efficient leukocyte attachment to the endothelium. In our study, the administration of busulfan was found not to affect the percentage of non–platelet-bound leukocytes expressing VLA-4 or CD11b, confirming that the method of platelet depletion was not toxic to leukocytes.

Rheologic evidence also suggests that leukocyte activation and subsequent integrin expression, after tethering to platelets, is a plausible mechanistic explanation by which platelets are a requisite factor in leukocyte recruitment because platelet–leukocyte collisions occur with greater frequency than leukocyte–endothelium collisions in conditions of laminar flow.29 Physiologic flow includes a redistribution of blood elements by which the density of platelets and leukocytes rapidly increases around the vessel periphery.29 This zone “traps” leukocytes into an environment rich in platelets, thus greatly enhancing the possibility of collisions between platelets and leukocytes. This may lead to the tethering of platelets to leukocytes to form rosettes through P-selectin–recognition steps, to up-regulate integrin expression, and to accelerate the action of firm adhesion to endothelium as platelet-bound leukocytes enter the capillary network.

Direct observation of membrane tethering between neutrophils and platelets has been demonstrated under physiologic flow conditions,32 and activated platelets have been shown to bind monocytes, polymorphonuclear (PMN) cells, eosinophils, basophils, and T cells.33,34 in a process involving a P-selectin–dependent recognition step.35 The stimulation of platelets with thrombin has been shown to induce the formation of rosettes around eosinophils in eosinophil–platelet suspensions, an action that was prevented by the inclusion of P-selectin monoclonal antibody.19 The P-selectin released from α granules and exported to the surfaces of platelets is the likely effector of the interaction with eosinophils because soluble P-selectin in plasma is predominantly monomeric and has a lower binding affinity for the P-selectin counter-ligand PSGL-1.36 This cellular interaction may result in the increased expression of integrins on leukocytes,35 and it produces platelet–leukocyte complexes that become the most adhesive cells (respective to their type) in the circulation.37

Recent observations, obtained from studies using whole blood exposed to hydrodynamic shear, comparable to that of the venous circulation, have confirmed that platelet adherence to PMN cells by P-selectin binding resulted in MAC-1–dependent platelet–PMN cell aggregation.38 Two previous reports have also shown the requirement of an intermediate activating signal from platelets themselves for the integrin to become functionally competent in binding to the counterreceptor, either with the platelets immobilized to a surface15 or activated in suspension.35 Thus, platelets are implicated in delivering an activating signal to leukocytes between rolling movement, tethering to endothelium, and firm attachment. Evidence supports a direct role for P-selectin in this scenario because purified P-selectin stimulated MAC-1–dependent platelet adhesion to human PMN cells39 and LFA-1 MAC-1–dependent adhesion of murine PMNs to intercellular adhesion molecule-1 (ICAM-1).40

In addition, P-selectin on activated platelets has been shown to be necessary for the presentation of inflammatory mediators (for example, RANTES) to monocytes, allowing RANTES-dependent monocyte recruitment to atheromatous lesions24,41 in a process that requires the formation of circulating platelet–monocyte aggregates.

In conclusion, the present study has demonstrated the requirement for factors expressed on the surfaces of activated platelets in the pulmonary recruitment of eosinophils and lymphocytes in a murine model of asthma, among which P-selectin plays a crucial role. It is, therefore, conceivable that the mechanism by which platelets induce the efficient attachment of eosinophils and lymphocytes to the endothelium, the first step in their transmigration to the inflamed tissue, is through P-selectin–dependent contact in the circulation, inducing the up-regulation of adhesion molecules on leukocytes.
