The N-terminal 11 amino acids of human erythrocyte band 3 are critical for aldolase binding and protein phosphorylation: implications for band 3 function

Silverio Perrotta, Adriana Borriello, Andrea Scalonli, Lucia De Franceschi, Anna Maria Brunati, Francesco Turrini, Vincenzo Nigro, Emanuele Miraglia del Giudice, Bruno Nobili, Maria Luisa Conte, Francesca Rossi, Achille Iolascon, Arianna Donella-Deana, Vincenzo Zappia, Vincenzo Poggi, William Anong, Philip Low, Narla Mohandas, and Fulvio Delia Ragione

The 911 amino acid band 3 (SLC4A1) is the major intrinsic membrane protein of red cells and is the principal Cl\(^{-}\)/HCO\(_3\)\(^{-}\) exchanger. The N-terminal cytoplasmic domain of band 3 anchors the spectrin-based membrane skeleton to the lipid bilayer through its interaction with ankyrin and also binds glycolytic enzymes and hemoglobin. We identified a son of a consanguineous marriage with severe anemia in association with marked deficiency of band 3 (12% ± 4% of normal).

Direct nucleotide sequencing of SLC4A1 gene demonstrated a single base substitution (T → C) at position + 2 in the donor splice site of intron 2, resulting in the generation of a novel mutant protein. Biochemical characterization of the mutant protein showed that it lacked the first 11 N-terminal amino acids (band 3 Neapolis). The expression of the mutant protein resulted in the complete absence of membrane-bound aldolase, and the mutant band 3 could not be tyrosine phosphorylated. The ability of the malarial parasite P falciparum to invade these red cells was significantly decreased. The identification of a novel band 3 mutant and its structural and functional characterization enabled us to identify pivotal roles for the 11 N-terminal amino acids in several protein functions and, in turn, in red-cell physiology. Introduction

The 911 amino acid human erythrocyte AE1 (eAE1) Cl\(^{-}\)/HCO\(_3\)\(^{-}\) exchanger SLC4A1 (commonly referred to as band 3) is the major integral membrane protein of red cells and serves to increase the total CO\(_2\)-carrying capacity of the blood.\(^1,2\) The SLC4A1 gene is transcribed in red-cell precursors under the control of an erythroid-specific promoter upstream of exon 1.\(^3\) AE1 also is expressed at high levels in type A intercalated cells of the collecting duct (kAE1). The renal transcripts arise from a distinct promoter located within intron 3 of SLC4A1,\(^3,4\) and the resultant kAE1 transcript encodes a protein that lacks the N-terminal 65 amino acids present in the protein expressed in erythrocytes.\(^5\)

Band 3 is characterized by 3 distinct structural and functional domains: (1) the membrane spanning domain, which traverses the bilayer and functions as a chloride/bicarbonate exchanger; (2) the short C-terminal cytoplasmic domain that binds carbonic anhydrase II, and (3) the N-terminal cytoplasmic domain that interacts with a number of proteins, including ankyrin, protein 4.2, protein 4.1, glycolytic enzymes (eg, aldolase and glyceraldehyde-3-phosphate dehydrogenase [GAPDH]), hemoglobin, hemichromes, and different protein tyrosine kinases.\(^1,2,6-13\) Furthermore, band 3 has recently been shown to assemble a macromolecular protein complex of integral proteins including the Rh complex (Rh-associated glycoprotein, Rh polypeptides, CD47, and glycophorin B) and glycophorin A.\(^14\)

The majority of the human SLC4A1 mutations reported to date\(^2,7\) result in autosomal-dominant forms of hereditary spherocytosis (HS) as a consequence of moderate decrease in membrane content of eAE1 protein. Importantly, in all these cases of HS...
The availability of knock-out animal models enabled the identification of the effect of complete deficiency of eAE1 on red-cell physiology. Band 3 null red cells have been described in a natural strain of cattle and in 2 strains of knock-out mice.15,17 Marked membrane loss leading to spheroctytic morphology is a feature of red cells in these animals. In addition to the absence of band 3, the mouse red cells also exhibit complete deficiency of glycoporphin A.15,18,19 In mice, the absence of band 3 leads to a severe life-threatening hemolytic anemia. So far, only one case of complete deficiency of band 3 in humans has been described. In this case, both the erythrocytic and kidney band 3 were absent, resulting in life-threatening neonatal anemia and distal renal tubular acidosis.20

Here we report a novel variant of eAE1, called band 3 Neapolis, in which N-terminal 11 amino acids are truncated. In the homozygous state, red-cell membranes contain only the mutant protein albeit at a much lower level. Detailed biochemical and functional characterization of these red cells has enabled us to obtain novel insights into the function of the N-terminal domain of band 3.

Materials and methods

Studies on SLC4A1 gene and band 3 cDNA

Blood samples were drawn from healthy volunteers, the proband, and his parents. The study was approved by the Institutional Review Board of the Second University of Naples, and was performed in accordance with the World Medical Association’s Declaration of Helsinki of 1975, as revised in 2000. Written informed consent to molecular genetic analysis, data analysis, and publication was obtained from all of the participants. DNA and total reticulocyte RNA were isolated as previously described.21 Sequencing of band 3 genomic DNA and cDNA was performed as previously reported.21,22

Antibodies and immunoblotting

Monoclonal antibodies to band 3, alpha and beta spectrin, glycophorin A (GPA), and glycophorin C (GPC) were obtained from Sigma (Sigma Chemical, St Louis, MO). Polyclonal antibodies to aldolase, GAPDH and CD47, were provided by Santa Cruz Biotechnologies (Santa Cruz, CA). A monoclonal antibody (CDB3) directed against the N-terminus of band 3 was previously described.23 Immunoblotting was performed according to the protocols reported previously.21,22

Polymerase chain reaction (PCR) analysis

Reticulocyte RNA was reverse transcribed to obtain random-primed cDNA using Moloney murine leukemia virus–reverse transcriptase (MMLV-RT) (Gibco-Invitrogen, Carlsbad, CA). The PCR conditions and the primers employed for amplification of cDNA were as follows: 5'-aaggtgagggagaggaagctggc-3' (forward); 5'-ctctactacgctgctctcagag-3' (reverse): 18 to 30 cycles with each cycle, consisting of 95°C for 30 seconds, 55°C for 1 minute, and 68°C for 30 seconds. In order to use the same amount of cDNA in each reaction, GAPDH amplification was performed first for normalization purposes as previously reported.26 All reaction products were run on 2% Tris borate EDTA (ethylenediaminetetraacetic acid) (TBE)–agarose gel stained with ethidium bromide. Normally spliced band 3 PCR product (exon1-exon2-exon3) was 216 bp long, while mutant band 3 products were 132 bp (exon1-exon3) and 341 bp (exon1-exon2-intron2-exon3).

To perform real-time RT-PCR on reticulocyte cDNA, we synthesized the following primers: SLC4A1/e1AF, 5'-agggaccctgaggctcgtgaggatgatt-3'; SLC4A1/e1AR, 5'-tcttttcataatcatcctgcagct-3'; SLC4A1/e2AF, 5'-tcacagccacctagccagagccact-3'; and SLC4A1/e2AR, 5'-aagggaccctgaggctcgtgagcag-3'.

Combinations of these primers were used to set up 5 different reaction mixtures: (1) SLC4A1/e1AF and SLC4A1/e2-3R that will generate a product of 113 bp derived by the correct joining of exons 1-2-3, since the reverse primer can only anneal to the junction 2-3; (2) SLC4A1/e1BF and SLC4A1/e2-3R that will generate a product of 120 bp with a different forward primer but correct joining of exons 1-2-3; (3) SLC4A1/e1-3F and SLC4A1/e4R that will generate a product of 132 bp derived by the skipping of exon 2 and the aberrant joining of exons 1-3-4, since the forward primer can only anneal to the junction 1-3 and the reverse primer is located in exon 4; (4) SLC4A1/i2F and SLC4A1/e4R that will generate a product of 147 bp derived by the retention of intron 2 and the aberrant joining of exon2-intron2-exon3-exon4, since the forward primer can only anneal to intron 2 and the reverse primer is located in exon 4; and (5) SLC4A1/e1BF and SLC4A1/i2R that will generate a product of 129 bp derived by the retention of intron 2 and the aberrant joining of exon1-exon2-intron2, since the forward primer is placed on exon 1 and the reverse primer will anneal to intron 2. The use of these 5 sets (1 to 5) enabled us to identify the normal allele (1 and 2), and the mutant alleles, skipping of exon 2 (3) and the retention of intron 2 (4) and (5). All PCR reactions were carried out using a Bio-Rad iCycler (Bio-Rad, Hercules, CA) with the following program: 95°C for 30 seconds, 63°C for 2 minutes, and 72°C for 1 minute. SYBR green was used to monitor DNA synthesis. We assessed control cDNA as well as cDNA from the parents and the proband and normalized all values assuming the wild-type allele in control as 100%

Red-cell membrane protein analysis

Red-cell ghosts were prepared according to the procedure of Dodge et al,27 except that 5 mM phenylmethylsulfonyl fluoride was added during the lysis step. Protein concentrations were determined by the procedure of Lowry et al,28 using a sodium carbonate solution containing 3% sodium dodecyl sulfate (SDS) and bovine serum albumin as a standard. Membrane proteins were analyzed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE).29,30 The gels were stained with Coomassie blue G. Erythrocyte membrane proteins were quantified by scanning of SDS-PAGE gels and through analysis of immunoblots as previously described.31,32 Band 3 was also quantified by labeling membranes with eosin maleimide followed by protein solubilization and fluorescence measurement (522 nm, excitation; 550 nm, emission).33

Band 3 purification

Band 3 monoclonal antibody (Sigma) directed against the 300 N-terminal amino acids was cross-linked to protein A–agarose essentially as described.34 Band 3 was solubilized by suspending the membranes in 1% (wt/vol) Triton X-100, 5 mM phosphate, pH 8, for 1 hour. After centrifugation at 30 000 × g for 30 minutes, the supernatant was diluted 10-fold and applied directly to the immunonaffinity column, previously equilibrated with 0.1% Triton X-100, 5 mM phosphate. The column was washed with 10 column volumes of 0.1% Triton X-100, 5 mM phosphate, and band 3 was eluted with 0.1 M glycine–HCl. Fractions of 300 μL were collected, and the protein composition of each of the collected fractions was analyzed by SDS-PAGE and Western blotting as previously reported.25 Fractions containing the pure band 3 protein were pooled and used for mass spectrometry analysis.

The N-terminal band 3 peptide of the control, heterozygous parents, and homozygous proband was prepared by digesting the membranes with trypsin (15 μg/mL) in 5 mM phosphate pH 8, 0.14 M NaCl for 2 hours at 4°C; the reaction was stopped by the addition of trypsin inhibitor. Digests were then centrifuged at 30 000 × g for 30 minutes, and the supernatant containing the N-terminal peptide was purified by affinity chromatography. Fractions containing the highest concentration of the peptide were analyzed by Western blotting to compare the apparent molecular weights of N-terminal peptides of normal and mutant band 3.
MALDI-TOF mass spectrometry analysis
Bands from SDS-PAGE were excised from the gel, trituated, and washed with water. Proteins in situ in the gel were reduced, S-alkylated with iodoacetamide, and digested with endoprotease AspN, as previously reported. On the basis of the primary structure of the protein, this protease was selected to be optimal for obtaining N-terminal sequence information on band 3. Digested aliquots were subjected to a desalting/concentration step using μZipTipC18 (Millipore, Bedford, MA) before MALDI-TOF mass spectrometry analysis. Peptide mixtures were loaded on the instrument target, using the dried droplet technique and α-cyano-4-hydroxycinnamic acid as matrix, and analyzed by using a Voyager-DE PRO mass spectrometer (Applied Biosystems, Framingham, MA). Spectra were acquired in the reflectron mode. Assignment of the recorded mass values to individual peptides was performed on the basis of their molecular mass and protease specificity.

Electron microscopy
An aliquot of proband red cells was fixed overnight in 25% glutaraldehyde and postfixed in 1% osmium tetroxide in 0.1 M sodium-cacodylate buffer for 2 hours. The sample was dehydrated in a graded ethanol series, dried at the critical point, coated with gold, and examined with a Cambridge Stereoscan 260 scanning electron microscope (SEM; Altran, Boston, MA) operating at 15 kV.

The image in Figure 3D was captured at 2170 ×, and the working distance (WD) was 8 mm. The total length of the images corresponds to 50 μm. The image was acquired by a ScanMaker 6800 scanner equipped with a transparency adapter (Microtek USA, Carson, CA), and the scanned images were processed using Adobe Photoshop 7.0 (Adobe Systems, San Jose, CA).

Quantitation of anion transport
Washed erythrocytes were subjected to assays of unidirectional disodium [35S] sulfate (Du Pont, Hertfordshire, United Kingdom) uptake in the absence or in the presence of 10 μM of the anion transport inhibitor di-isothiocyanato-dihydrostilbene disulphonate (Sigma), as previously described. Each flux study using the proband’s red cells was performed in parallel using red cells from the parents and from unrelated healthy subjects. The sulfate flux was expressed for a constant number of cells (1 × 10^11 cells) in order to appropriately compare flux values for samples with variable mean corpuscular volume (MCV) values. The within- and in-between run variation coefficients (CVs) for these measurements were less than 5%.

Phosphorylation of band 3
[y32P] adenosine triphosphate (ATP) was purchased from Amersham (Arlington Heights, IL). Anti–P-Tyr antibody was purchased from ICN (Arlington Heights, IL). Anti–P-Tyr antibody was purchased from ICN (Arlington Heights, IL). The liver is enlarged, and the red blood cell indices are: red blood cell (RBC) count 3.0 × 10^12/L, Hb 90 g/L, Htc 27%; MCV 91 fL, MCH 31 pg, MCHC 34 g/dL; and reticulocytes 10%. The blood smear shows a wide range of abnormal red-cell morphologies, including stomatocytes, spherocytes, and microcytes. Since a mild form of autosomal dominant HS due to band 3 deficiency was noted in both parents, the proband was analyzed for a possible SLC4A1 homozygous mutation. Direct nucleotide sequence of SLC4A1 gene showed a single base substitution (T→C) at position +2 in the donor splice site of intron 2 (Figure 1A). The observed mutation abolishes a BspMI restriction site. The novel variant is designated as band 3 Neapolis.

RT-PCR analysis of reticulocyte mRNA was performed using primers located in SLC4A1 exons 1 and 3. A 215-bp product was obtained in the control, while 2 amplified fragments of 340 bp and 132 bp were noted in the patient (Figure 1B). Sequencing analysis revealed that the 340 bp resulted from the retention of intron 2, while the 132-bp fragment is the result of skipping of exon 2 (Figure 1C). All 3 amplified fragments (340, 215, and 132 bp) were noted in the parents (Figure 1B). Quantitative evaluation of the various transcripts using real-time PCR of reticulocyte RNA showed that in the proband, as expected, no normal mRNA was present, and each of the 2 mutant mRNAs was present at 11% to 13% of normal levels. In the heterozygous parents 52% of the message was of wild type, with 6% each of the 2 mutant transcripts. The retention of intron 2 leads to a premature termination of translation after the 19th triplet, while skipping of exon 2 results in the loss of the normal translation start site for erythroid band 3

Results
A new SLC4A1 mutation, band 3 Neapolis, causes aberrant mRNA splicing
A 21-month-old child, the second son of a consanguineous marriage, was referred for the evaluation of a life-threatening nonimmune hemolytic anemia. The patient was transfusion depen-
(Figure 1D). Thus, the first alternative splicing event can generate only a very truncated form of altered erythroid band 3, while the second splicing event will generate a mutant form of band 3 with an altered N-terminal. Due to the location of the mutation, kidney band 3 expression will be unaffected and, consistent with this expectation, no defect in the distal urinary acidification in the homozygous child was noted (data not shown).

Band 3 Neapolis gene encodes a protein lacking the 11 N-terminal amino acids

As the aberrant splicing pattern of mutant gene suggested the generation of an altered protein in the red cells of the proband, we biochemically characterized band 3 from the proband’s red cells. SDS-PAGE immunoblotting experiments showed that the mutant band 3 migrated slightly faster than the normal protein, suggesting a decreased molecular weight and that the band 3 content of the membrane was significantly reduced (data not shown). To substantiate the altered mobility of the mutant band 3, isolated red-cell membranes were digested with trypsin for 2 hours, and the supernatant of the digests was passed over a column of protein A sepharose cross-linked to a monoclonal antibody raised against the first 300 amino acids of band 3 to obtain purified N-terminal fragments. Western blot analysis of the various purified fragments clearly showed that the apparent molecular weight of the N-terminus of mutant band 3 was smaller than that of the normal (Figure 2A). Interestingly, the red-cell membranes from the heterozygous parents showed only the normal N-terminal fragment of the protein, implying an apparent lack of assembly of the mutant band 3 in these membranes (Figure 2A).

Although the DNA analysis precisely identified the mutation in the band 3 Neapolis gene, it did not provide definitive information on the nature of the truncated protein product. While the normal translation initiation ATG is deleted due to skipping of exon 2, there are at least 3 different ATG triplets in exon 3, which could function as the starting codon for the synthesis of mutant band 3 (Figure 2B). The first 2 ATGs are located at codons 11 and 12, and their use should result in the lack of either 10 or 11 amino acids at the N-terminus, respectively, while the use of the third ATG located at codon 31 would result in the loss of 30 amino acids at the N-terminus (Figure 2B).

To characterize the N-terminus of the mutant protein, normal and mutant band 3 were purified to homogeneity by immunoaffinity techniques, reduced, alkylated, and digested with endoprotease AspN. The resulting digests were subjected to peptide mapping analysis by MALDI-TOF mass spectrometry. As shown in Figure 2C, the spectra obtained from normal band 3 showed distinct peaks at m/z 3335.3031, 3351.3044, and 3367.3101 that correspond to the expected peptide(26-37) and its oxidized products. While these signals are absent in the spectra of mutant protein, unique signals at m/z 3335.3031, 3351.3044, and 3367.3101 were noted instead. On the basis of their molecular mass and protease specificity, these peaks can be assigned to a protein with a modified N-terminus and, in particular, to peptides (12-22), (12-24), (12-37), and oxidized (12-37) all bearing acetylated Met12 as the N-terminal residue. These findings enabled us to definitively demonstrate that the truncated mutant band 3 is devoid of the first 11 amino acids and that it is generated through the use of the second ATG in exon 3. Interestingly, the resulting N-terminal residue Met12 is acetylated, as is the case for normal Met1. A definitive confirmation for the absence of 11 N-terminal amino acids in the mutant band 3 was obtained by Western blot analysis using a monoclonal antibody directed against this region. As shown in Figure 2D, while Western blot analysis readily detected normal band 3 in membranes of red cells from healthy subjects and the parents, it failed to detect mutant band 3 in membranes of red cells from the proband.

Red cells of the homozygous band 3 Neapolis contain a reduced amount of the truncated protein and show altered membrane function

Following the detailed biochemical characterization of the mutant band 3, we investigated the effect of this genetic alteration on the various red-cell membrane and cellular functions. Band 3 content of red-cell membranes of the proband and parents was determined by 3 different methodologies, namely SDS-PAGE analysis, immunoblotting analysis, and eosine maleimide labeling of band 3 in intact red cells. Band 3 content of the membrane proteins assayed by SDS-PAGE or immunoblotting analysis was normalized to

![Figure 2. Band 3 Neapolis protein analysis.](image)
while that of red cells from the heterozygous parents was 82% of red-cell membranes of the proband was 12% independent on the band 3 complex. Band 3 and protein 4.2 content complex (GPC, protein 4.1 and p55) is thought to be distinct and protein 4.1 and GPC contents of the membrane since the GPC cells were separated by SDS-PAGE41 and the gel stained by Coomassie blue G. (B) (A) SDS-PAGE analysis of red-cell membrane proteins. Membrane proteins of red cells were separated by SDS-PAGE41 and the gel stained by Coomassie blue G. (B) Immunoblotting of band 3. The membrane content of band 3 was determined by immunoblotting, using an anti–band 3 monoclonal antibody. Equivalent amounts of membrane proteins were loaded, based on the GPC content. (C) Immunoblotting of GAPA and GPC and CD47. Red-cell membrane content of GAPA, GPC, and CD47 was evaluated by immunoblotting, using monospecific antibodies. (D) Scanning electron micrograph of red cells of the proband. (E) Quantitation of anion transport. DIDS-sensitive unidirectional disodium [35S] sulfate uptake in red cells of normal and proband red cells.

The 11 N-terminal amino acids of band 3 are critical for the binding of glycolytic enzymes and for the in vivo protein phosphorylation

The cytoplasmic domain of band 3 is the anchoring site for several red-cell glycolytic enzymes such as aldolase, GAPDH, and phosphofructokinase and is also a substrate for the protein tyrosine kinase, Syk.41,42 Several nuclear magnetic resonance (NMR) studies provided important insights into the structure and function of the 11 N-amino terminal amino acids in solution. It is inferred that the structure of this region forms a loop consisting of residues 4 through 9 in which the phenolic ring of Y8 is sandwiched between the methyl groups of L4 and M12.41,42 Phosphorylation of tyrosine 8 destabilizes the intermolecular protein-protein association, particularly between band 3 and glycolytic enzymes.43

Since the naturally occurring band 3 Neapolis assembled on to the red-cell membrane lacks these N-terminal 11 amino acids, we explored the altered function of this domain in the context of intact red-cell membrane. The association of aldolase with band 3 in the membranes of red cells from the proband and from healthy subjects was assessed. In contrast to the strong association of aldolase with intact normal membranes, no aldolase could be detected in association with membranes of red cells from the proband (Figure 4A). This lack of association was not due to absence of aldolase in

Figure 4. Band 3 Neapolis functions: binding of glycolytic enzymes and protein phosphorylation. (A) Aldolase binding to normal and mutant band 3. Red-cell membrane proteins from a healthy subject and the proband were separated by SDS-PAGE, transferred to a nitrocellulose paper, and analyzed by immunoblotting using an anti-aldolase antibody. (B) Sequential phosphorylation of band 3 in vitro. Red-cell membrane proteins were subjected to various treatments as outlined. Specifically, ghosts were incubated with Syk (lane 2) or with Lyn (lane 3) or without the enzymes (lane 1). Phosphate incorporation was evaluated on the basis of 32P signal (determined by exposing dried gels to x-ray films). In lanes 4, 5, and 6, membranes that were previously treated with Syk in the presence of unlabeled phosphate were incubated with Syk (lane 5) or with Lyn (lane 6) in the presence of labeled phosphate. Lane 4 is a control without addition of either Syk or Lyn. (C) Phosphorylation of band 3 in vivo. Red blood cells were incubated in the absence or presence of diamide. Cell membranes were isolated, solubilized, and submitted to SDS-PAGE followed by transfer to nitrocellulose. The upper part of blot shows immunostaining of band 3 with antiphosphotyrosine antibody. The filter was stripped and reprobed with anti–band 3 antibody (bottom panel). Nor indicates control membranes; Prob, proband membranes.

protein 4.1 and GPC contents of the membrane since the GPC complex (GPC, protein 4.1 and p55) is thought to be distinct and independent on the band 3 complex. Band 3 and protein 4.2 content of red-cell membranes of the proband was 12% ± 4% of normal, while that of red cells from the heterozygous parents was 82% ± 6% of normal (Figure 3A,B and data not shown). Eosine maleimide labeling showed that the band 3 content of proband red cells was 13% ± 3% of normal. GPA and CD47 content of the membrane also were markedly reduced to 11% ± 5% and 42% ± 10% of normal, respectively (Figure 3C). The membrane content of α-spectrin, β-spectrin, and ankyrin also was reduced but to a much lesser extent, 79% ± 3%, 81% ± 4%, and 75% ± 6% of normal, respectively (Figure 3A). A marked reduction in the membrane content of GAPDH (corresponding to band 6) also was noted (Figure 3A).

The consequences of the marked deficiency of band 3 on red-cell morphology were significant. Stomatocytes and spherocytes were the dominant morphologic features revealed by scanning electron microscopy of mutant red cells (Figure 3D). In addition, there were also a number of microspherocytosis and membrane protrusions similar to those reported in band 3 null mouse red cells.15,16,39 Osmotic gradient ektacytometry40 confirmed a marked increase in osmotic fragility of the red cells as a consequence of a significant reduction in membrane surface area of mutant red cells (data not shown).

Using 4,4'-diisothiocyanato-dihydrostilbene-2,2'-disulphonate (DIDS), a specific inhibitor of the anion transporter, we evaluated the anion transport activity of red cells with mutant band 3. The DIDS sensitive sulfate influx was reduced to 10% of normal in red cells from the proband and to 78% of normal in the heterozygous parents (Figure 3E and data not shown). As the extent of reduction in anion transport activity was proportional to the extent of decrease in membrane content of band 3, this finding implies that the mutant band 3 retained its ability to transport anions.
red cells, since the total aldolase content of cells was similar in red cells from healthy subjects and from proband (data not shown). This finding implies that N-terminal 11 amino acids are critical for association of aldolase with band 3 in intact red-cell membranes.

We next explored whether Syk tyrosine kinase could recognize the truncated band 3 as a substrate in vitro by assessing the ability of Syk purified from normal erythrocytes to phosphorylate band 3. As shown in Figure 4B, in spite of the absence of 1 of 2 phosphorylation sites (Tyr8), the mutant protein was phosphorylated in vitro by the exogenously added purified enzyme (lane 2). The extent of Syk-phosphorylation, determined using equivalent amounts of normal and mutant band 3, showed that the phosphorylation of the mutant protein was approximately 50% of normal (data not shown), consistent with the presence of a single phosphorylation site in the mutant protein at Tyr21. Furthermore, we were able to document that the presence of the single phototyrosine docking site at Tyr 21 is sufficient for the interaction of band 3 with the SH2 domain of Lyn and subsequent phosphorylation of the truncated band 3 (Figure 4B, lanes 3, 6). To establish whether these in vitro phosphorylation events can be recapitulated in intact cells, we stimulated red cells from the proband and from healthy subjects with diamide to induce tyrosine phosphorylation of band 3. As shown in Figure 4C, while band 3 was tyrosine phosphorylated in normal red cells, no phosphorylation could be detected in proband’s red cells. These findings imply an absolute requirement for Tyr8 for band 3 phosphorylation in vivo in intact membranes.

Malaria parasite life cycle is altered in band 3 Neapolis erythrocytes

Previous studies using various peptides corresponding to the extracellular loops of band 3 have suggested an important role for band 3 in red-cell invasion by *P. falciparum*. To further substantiate a requirement for band 3 in parasite invasion, we assayed the ability of 2 different strains of *P. falciparum* to invade red cells of the proband with markedly reduced membrane content of band 3. As shown in Table 1, invasion and maturation of the parasites were markedly inhibited in red cells of the proband. The decreased invasion and maturation could be seen at 24 hours (early stage during first cycle of invasion), at 48 hours (late stage during first cycle of invasion), and at 72 hours (early stage during second cycle of invasion). The ability of parasites to invade red cells of the parents was not significantly different from that of normal red cells (Table 1). These findings establish an important role for band 3 in red-cell invasion by *P. falciparum*.

Cultures were inoculated by the addition of purified schizont-stage parasitized normal red cells (purity more than 95%) to test red cells suspended in growth medium (hematocrit, 0.5%). Two strains of parasite (Palo alto and FCR3) were used in each case. After 24 hours (ring stage of first cycle), 48 hours (trophozoite stage of the first cycle), and 72 hours (ring stage of second cycle) of culture, slides were prepared and stained with Diff-Quik parasite stain, and stage-dependent parasitemia was assessed by microscopic inspection. Values are expressed as percent of parasitized red cells during the course of the experiment. In parentheses, growth is normalized assessing 100% growth for the control.

**Discussion**

In the present study, we have identified and characterized a new variant of human red-cell AE1 protein, designated band 3 Neapolis, that provides novel insights into the role of the N-terminal amino acids in regulating protein function. A single base substitution (T → C) at position +2 in the donor splice site of intron 2 was identified as the mutation responsible for band 3 Neapolis. The mutation causes altered splicing of AE1 gene with the consequent generation of 2 different mature band 3 mRNAs, one that includes intron 2 and the other that skips exon 2. Both transcripts are produced, since the GU to GC mutation does not completely abrogate its ability to function as a donor splice site. In fact, a minority of genes (approximately 1%) use the GC donor splice site instead of the canonical GU donor splice site. Only the shorter mRNA that skips exon 2 is translated into a protein that is assembled into the red-cell membrane. Mass spectrometric analysis showed that the membrane-assembled mutant band 3 lacked the first 11 N-terminal amino acids due to elimination of the normal start site in exon 2 and the use of an alternate start site in exon 3. Importantly, the red-cell membrane content of the mutant band 3 is dramatically decreased to 12% of normal. As such, the red cells of the proband exhibit both a qualitative defect and a quantitative deficiency of band 3. These band 3 defects thus account for the severe transfusion-dependent hemolytic anemia noted in the proband prior to splenectomy. Following splenectomy, the proband became transfusion independent with a moderately compensated hemolytic anemia. The quantitative deficiency of band 3 can account for the observed reduction in anion transport and loss of red-cell membrane surface area. As a result of the location of the mutation, only the synthesis of red-cell band 3 protein was affected, while the synthesis of the kidney form of band 3 was uncompromised, accounting for the normal renal function noted in the proband.

The mechanism responsible for the marked deficiency of mutant band 3 is not completely clear. Quantitative PCR showed a marked decrement in the number of mutant transcripts and a strong correlation between the amount of mutant mRNA and the membrane content of truncated protein. Thus, either a lower rate of transcription of the mutant gene or an intrinsic instability of the aberrant mRNA is likely to account for marked deficiency of the mutant protein in red cells. It is interesting, in this context, that red cells of heterozygous parents do not express detectable levels of band 3 Neapolis protein, in spite of the fact that they synthesize measurable amounts of altered mRNA. Similar findings have been reported for other AE1 mutations in the heterozygous state.

A major advantage of our analysis compared to earlier studies on red cells with quantitative deficiencies of band 3 is that for the first time we are able to assess the function of the N-terminus of band 3 in the context of an intact membrane. Our in vivo demonstration that the 11 N-terminal amino acids form the major binding site of aldolase and that other glycolytic enzymes (eg, GAPDH) employ different band 3 binding domains validates that this domain of band 3 is critical for recruiting aldolase to the red-cell membrane. These findings lend strong support to studies using normal red cells.

A second significant finding is the validation of a critical role for the 11 N-terminal amino acids in the sequential Tyr-phosphorylation of band 3 triggered by diamide stimulation. The observation that the truncated band 3 can be phosphorylated by Syk and thereby promote the recruitment of Lyn tyrosine kinase in vitro but not in vivo has major structural and functional implications. Our
findings provide strong evidence to support a critical role for Tyr8 and its neighboring amino acids in the overall control of the reversible band 3 phosphorylation in intact membranes. The observation also implies that the structural alterations involving both band 3 and the overall membrane architecture play a key role in phosphorylation of band 3 in vivo.

The finding that the red cells of the proband are resistant to malaria infection supports a pivotal role for band 3 in parasite invasion and maturation. As band 3 has been identified to be an important receptor for the merozoite surface protein MSP1, it is likely that deficiency of band 3 is responsible for the reduced invasion. However, we cannot rule out the potential contribution of an altered metabolic and/or redox state of red cells in defective invasion and maturation of the parasites in band 3-deficient red cells.

In addition to marked deficiency of band 3, red cells from the proband also exhibit deficiencies in protein 4.2 (10% of normal), glycophorin A (11% of normal), and CD47 (47% of normal). These findings are similar to those previously reported for the only case of glycophorin A (11% of normal), and CD47 (47% of normal). These proband also exhibit deficiencies in protein 4.2 (10% of normal), while the membrane content of glycophorin A is 29% of normal. As the presence of 10% of protein 4.2 could account for the significant difference in CD47 of the proband’s red cells compared with band 3 Coimbra erythrocytes. The presence of similar amounts of band 3 and protein 4.2 in membranes of red cells of the proband implies that the membrane content of protein 4.2 is exclusively determined by its interaction with band 3 and that the 11 N-terminal amino acids of band 3 are not involved in the binding of protein 4.2. Furthermore, the presence of significant amounts of ankryin in band 3 Neapolis membranes implies that the N-terminal 11 amino acids of band 3 are not required for band 3–ankryin interaction.

Despite the marked deficiency of band 3, spectrin, ankryin, and protein 4.1, the content of red cells from proband is very similar to normal, and the membrane skeletal architecture also appears to be normal. These findings further support the notion that band 3 is not essential for the stable biogenesis of membrane skeleton.

In summary, we identified a novel mutant band 3 (band 3 Neapolis) that lacks the first 11 N-terminal amino acids in association with hereditary spherocytosis. Detailed studies have enabled us to show that the mutant band 3 fails to bind aldolase but does bind other glycolytic enzymes and that the 11 N-terminal amino acids are critical for tyrosine phosphorylation of membrane-associated band 3. Furthermore, we established a key role for band 3 in malarial parasite invasion of human red cells.
