Defining the molecular mechanisms underpinning fetal (γ) globin gene silencing may provide strategies for reactivation of γ-gene expression, a major therapeutic objective in patients with β-thalassemia and sickle cell disease (SCD). We have previously demonstrated that symmetric methylation of histone H4 Arginine 3 (H4R3me2s) by the protein arginine methyltransferase PRMT5 is required for recruitment of the DNA methyltransferase DNMT3A to the γ-promoter, and subsequent DNA methylation and gene silencing. Here we show in an erythroid cell line, and in primary adult erythroid progenitors that PRMT5 induces additional repressive epigenetic marks at the γ-promoter through the assembly of a multiprotein repressor complex containing the histone modifying enzymes SUV4-20h1, casein kinase 2α (CK2α), and components of the nucleosome remodeling and histone deacetylation complex. Expression of a mutant form of PRMT5 lacking methyltransferase activity or shRNA-mediated knockdown of SUV4-20h1 resulted in loss of complex binding to the γ-promoter, reversal of both histone and DNA repressive epigenetic marks, and increased γ-gene expression. The repressive H4K20me3 mark induced by SUV4-20h1 is enriched on the γ-promoter in erythroid progenitors from adult bone marrow compared with cord blood, suggesting developmental specificity. These studies define coordinated epigenetic events linked to fetal globin gene silencing, and provide potential therapeutic targets for the treatment of β-thalassemia and SCD. (Blood. 2010; 116(9):1585-1592)

Introduction

The developmental switch in human β-like globin gene subtype from fetal (γ) to adult (β) that begins at birth heralds the onset of the hemoglobinopathies, β-thalassemia and sickle cell disease (SCD). The observation that increased adult γ-globin gene expression (in the setting of hereditary persistence of fetal hemoglobin [HPFH] mutations) significantly ameliorates the clinical severity of β-thalassemia and SCD has prompted the search for therapeutic strategies to reverse γ-globin gene silencing.1 To date, this has been achieved through pharmacologic induction, using compounds that broadly influence epigenetic modifications, including DNA methylation and histone deacetylation.2,4 The development of more targeted therapies is dependent on the identification of the molecular mechanisms underpinning fetal globin gene silencing. These mechanisms have remained elusive, despite exhaustive study of the HPFH mutations,5 and considerable progress in many other aspects of globin gene regulation.

Central to silencing of the γ-genes is DNA methylation, which marks critical CpG dinucleotides flanking the γ-gene transcriptional start site in adult bone marrow erythroid cells.6,7 We have recently shown that these marks are established as a consequence of recruitment of the DNA methyltransferase, DNMT3A to the γ-promoter by the protein arginine methyltransferase PRMT5.8 PRMT5 induces the repressive histone mark, H4R3me2s, which serves as a template for direct binding of DNMT3A, and subsequent DNA methylation. Loss of PRMT5 binding, or its enzymatic activity leads to demethylation of the CpG dinucleotides and γ-gene activation.8

Here we demonstrate that, in addition to the H4R3me2s mark and DNA methylation, PRMT5 binding to the γ-promoter, and its enzymatic activity are essential for assembly of a multiprotein complex on the γ-promoter, which induces a range of coordinated repressive epigenetic marks. Disruption of this complex leads to reactivation of γ-gene expression. These studies provide a platform for the development of targeted therapies for β-thalassemia and SCD.

Methods

Cell culture

K562 cells were grown as described previously.9 Human bone marrow (BM) and cord blood (CB) were collected after approval by the Melbourne Health and Royal Women’s Hospital Human Research Ethics Committees. CD34+ cells isolated from fresh adult BM and CB were cultured in Iscove modified Dulbecco medium supplemented with 15% (vol/vol) fetal calf serum, stem cell factor (SCF; 100 ng/mL), interleukin-3 (10 ng/mL), and FMS-like tyrosine kinase-3 ligand (500 ng/mL) for 7 days, followed by erythropoietin (EPO; 5 U/mL) alone for 5 days to induce erythroid differentiation. To induce high levels of γ-gene expression in CB, the culture conditions described by Bhanu et al were used.10 Briefly, cells were grown in Dulbecco modified Eagle medium containing 30% (vol/vol) fetal bovine serum, 1% bovine serum albumin (wt/vol), β-mercaptoethanol (10-3M), dexamethasone (10-7M), transferring (0.3 mg/mL), glutamine (2mM), EPO (4 U/mL), SCF (50 ng/mL) and transforming growth...
factor-B1 (1.25 ng/mL). For low fetal hemoglobin conditions for adult BM, the culture conditions described by Sankaran et al.11 Briefly, cells were grown in StemSpan SFEM medium with 1× CC100 cytokine mix for 6 days and then reseeded into the same medium supplemented with SCF (20 ng/mL), EPO (1 U/mL), interleukin-3 (5 ng/mL), dexamethasone (2 × 10⁻⁶M), and β-estradiol (10⁻⁶M). Cell-surface marker analyses with CD71 and Glycophorin A indicated that cultured cells were greater than 90% erythroid lineage.

Protein interaction studies

Immunoprecipitation and immunoblotting were performed as described previously.12 Antibodies used in the immunoprecipitations: FLAG (Sigma-Aldrich), PRMT5, CK2α, SUV4-20h1, SUV39h1, MBD2, MeCP2 (Abcam), Mi2, mSin3A, DNMT1, DNMT3A, DNMT3B, MBD3, Brg-1, HP1, tubulin, GATA-1 (Santa Cruz Biotechnology), HDAC1 (Upstate Biotechnology). Many of these were also used in chromatin-immunoprecipitation (ChIP) assays.

Size exclusion chromatography

Size exclusion chromatography was performed on a calibrated Superose 12 HR 10/30 gel filtration column (Amersham/Pharmacia), and 500-μL fractions were collected. Fractions were concentrated by trichloroacetic acid precipitation, electrophoresed on a 10% sodium dodecyl sulfate–polyacrylamide gel electrophoresis, transferred to a polyvinylidene difluoride membrane, and analyzed by Western blot with selected antibodies.

ChIP analysis

ChIP assays were performed as described previously.8 Chromatin fractions from K562 cells, or erythroid progenitors from CB or BM were immunoprecipitated with specific antibodies (Abs). No antibody and normal rabbit immunoglobulin G (IgG) served as the controls. Antibodies used were: H4R3me2s, H4S1ph, H4K9me3, H3K27me3, SUV4-20h1, CK2α (Abcam), H4K5ac, H4K8ac, H4K12ac, H4K16ac (Upstate Biotechnology), and RNA pol II (Santa Cruz Biotechnology). The relative enrichment was calculated using the method described in Wysocka et al.13 The percentage of ChIP DNA was calculated relative to the input DNA. In all assays it ranged from 0.35% to 0.71%. In comparative experiments, the percentage of ChIP DNA was calculated relative to the input DNA. In all experiments, we confirmed the specificity of the ChIP by PCR with gene-specific primers (Figure 1A). Two other histone H4 modifications, H4S1ph15 and tri-methylation of H4K20 (H4K20me3)16 were also differentially localized to the γ-promoter in the 2 lines, with high levels observed in the PRMT5-f cells, and a marked loss in the PRMT5-kd line.

Protein interaction studies

We have previously established K562 cell lines in which FLAG-tagged PRMT5 expression is enforced (PRMT5-f; to greater than the endogenous levels), or in which expression of PRMT5 is markedly reduced (PRMT5-kd).8 To determine whether other repressive histone modifications were induced at the γ-promoter in response to increased PRMT5 expression, we performed ChIP analysis on our PRMT5-f and PRMT5-kd cells using a range of specific antibodies (Figure 1A). Two other histone H4 modifications that have been linked to gene silencing, phosphorylation of H4S1 (H4S1ph),15 and tri-methylation of H4K20 (H4K20me3)16 were also differentially localized to the γ-promoter in the 2 lines, with high levels observed in the PRMT5-f cells, and a marked
reduction in the PRMT5-kd line. Tri-methylation of H3K9, which has previously been shown to be required for H4K20me3,16 and tri-methylation of H3K27, which has been linked to DNA methylation and gene silencing,17,18 were also increased in the PRMT5-f compared with the PRMT5-kd lines, although these changes were less striking and so we focused on the H4S1ph and H4K20me3 modifications. The alterations in repressive marks were reflected in localization of RNA polymerase II (RNA polII) to the promoter, which was markedly reduced in the PRMT5-f cells compared with the knockdown cells. Assessment of histone H4 acetylation in the 2 cell lines revealed a substantial reduction in H4K12ac, and a modest loss of H4K8ac in the PRMT5-f cells, but no alterations at lysine 5 or 16.

We examined whether these repressive histone marks were dependent on the methyltransferase activity of PRMT5 by performing ChIP analyses on the K562 cells expressing PRMT5Δ-f, a FLAG-tagged mutant form of PRMT5, in which 5 amino acids in the S-adenosyl-L-methionine binding motif had been deleted19 (Figure 1B). The mutant form of PRMT5 retained the ability to bind robustly to the γ-promoter (as indicated by the FLAG ChIP), but not to induce the H4R3me2s mark. Concomitantly, we observed a distinct reduction of H4S1ph, H4K20me3, H3K9me3 and H3K27me3 at the γ-promoter, coincident with increased occupancy by RNA PolII in the PRMT5Δ-f-expressing cells. These findings indicated that the methyltransferase activity of PRMT5, and not just its physical occupation of the promoter, was integral for the subsequent generation of multiple repressive histone marks.

**Recruitment of a multiprotein repressor complex to the γ-promoter is dependent on PRMT5**

PRMT5 has been linked to transcriptional repression through the formation of 3 multiprotein complexes, 1 containing mSin3A, HDAC1, and HDAC2, another containing SWI/SNF components Brg1 and Brm, and a third containing MBDB/MBD3 and components of the nucleosome remodeling and histone deacetylation (NuRD) complex.20-23 To determine whether these factors associated with PRMT5 in K562 cells, we performed immunoprecipitations with extract from the PRMT5-f cells using the anti-FLAG antisera, and blotted the precipitates with antibodies to a range of components of the nucleosome remodeling and histone deacetylation (NuRD) complex.20-23 In the online article), we confirmed that these proteins formed a multiprotein complex assembled on the γ-promoter, which was integral for the subsequent generation of multiple repressive histone marks that were tested exhibited peak levels in the fractions containing PRMT5. We confirmed the localization of the complex components on the proximal γ-promoter by ChIP in K562 cells expressing PRMT5-f (Figure 2C). Binding of complex components extended to regions of the promoter and γ-gene immediately adjacent to the proximal promoter, but was not observed at more distal sequences, with the exception of DNMT3A, which still displayed a binding peak on the γ-promoter (supplemental Figure 1, available on the Blood Web site; see the Supplemental Materials link at the top of the online article). We confirmed that these proteins formed a multiprotein complex assembled on the γ-promoter using a ChIP-reChIP strategy, in which chromatin immunoprecipitated with normal rabbit immunoglobulin G (IgG) was used as a negative control. Abs used are indicated on the right. (B) Western blot analysis of proteins immunoprecipitated from K562 cells expressing PRMT5-f with α-FLAG antibodies (Abs). A mock immunoprecipitation with normal rabbit immunoglobulin G (IgG) was used as a negative control. Abs used are indicated on the right. (C) ChIP analysis on chromatin derived from PRMT5-f-expressing K562 cells with the stated Abs. (D) ChIP-ReChIP analysis on chromatin derived from FLAG immunoprecipitates from PRMT5-f K562 cells with the stated Abs. Each experiment was performed twice independently.

Abs used are indicated on the right.

Figure 4. Role of SUV4-20h1 in developmental globin gene silencing

Based on our expression and DNA methylation data, it appeared that SUV4-20h1 played a more central role in γ-gene silencing than CK2α. We therefore determined whether the H4K20me3 mark was evident at the human γ-globin promoter in a developmentally specific pattern in primary human cells, we isolated erythroid progenitors from CB and adult BM and cultured them in conditions that supported high levels of cellular expansion. ChIP analysis demonstrated a 2-fold increase in the H4K20me3 mark at the γ-promoter in adult BM erythroid progenitors compared with progenitors derived from CB (supplemental Figure 2). Our previous analysis of globin expression in cultured CB progenitors had demonstrated almost equivalent levels of γ- and β-globin expression,8 which may have accounted for the relatively modest differential in the H4K20me3 mark between these cells and BM progenitors. To address this, we cultured CB progenitors in conditions that promoted high levels of γ-gene expression,10 and BM progenitors in low fetal hemoglobin conditions11 (Figure 5A), and examined the H4K20me3 mark in these cells. In this setting, we observed a 4-fold difference in the H4K20me3 mark at the γ-promoter in adult BM erythroid progenitors compared with progenitors derived from CB (Figure 5B). We then examined the distribution of the H4K20me3 mark across the β-globin locus in these BM erythroid progenitors using primer pairs spanning regions of the locus control region (LCR) hypersensitive sites (HS1–4), the γ-, ε- and β-globin promoters, the intergenic region between the 5′-γ- and 5′-γ-genes, exon 3 of the β-gene, and the 3′HS (Figure 5C). Enrichment was observed at the γ- and ε-promoters compared with the β-promoter in these adult cells. We also observed increased levels at the HSs of the LCR, particularly at HS4 and HS5. To confirm the presence of the multiprotein complex
in BM erythroid progenitors we immunoprecipitated extract from these cells with PRMT5 antibodies, and blotted the precipitates with antibodies to selected complex components (Figure 5D left panel). Binding of PRMT5 to CK2α and SUV4-20h1 was readily detected, but we were unable to detect DNMT3A using this approach (not shown). However, coimmunoprecipitation of DNMT3A with PRMT5 in these extracts was demonstrated using the reverse order of antibodies (Figure 5D right panel).

To examine the functional role of SUV4-20h1 and PRMT5 in adult BM erythroid progenitors, we employed our specific shRNAs in lentiviral vectors to target the individual enzymes. Levels of SUV4-20h1 were reduced to 30% of a scrambled control (Figure A).

Figure 4. SUV4-20h1 mediates transcriptional silencing of the γ-gene. (A) Expression of SUV4-20h1 and (B) CK2α was analyzed in K562 cells expressing specific shRNAs or scrambled control sequences (scr). (C) H4K20me3 levels at the γ-promoter in SUV4-20h1-kd and scr control cells, and (D) H4S1ph levels at the γ-promoter in CK2α-kd and scr control cells were measured by ChIP analysis. The error bars correspond to the SD. Each experiment was performed twice independently. Normal rabbit IgG served as the control. (E) Analysis of γ-globin gene expression in SUV4-20h1-kd and scr control cells, and (F) CK2α-kd and scr control cells. (G) DNA methylation at the human γ-gene in SUV4-20h1-kd, CK2α-kd and scr control cells. Each row shows the methylation status of individual CpG dinucleotides derived from sequence analysis of 25 representative (of at least 40) individual cloned polymerase chain reaction (PCR) products of the γ-genes after bisulfite modification from knockdown or scr control K562 cells. The differences between the 2 knockdown lines and the scrambled control were highly significant (P < .05). The numbers at the top represent the positions of the CpG dinucleotides relative to the transcriptional start site of the γ-gene. (H) ChIP of the H4R3me2s level and (I) PRMT5 binding at the γ-promoter in SUV4-20h1-kd and scr control cells. Normal rabbit IgG served as the control. The error bars correspond to the SD. Each experiment was performed 3 times independently.
transferases, methyl-CpG binding proteins and methyl-interactions between lysine methyltransferases, and DNA methylation. These processes have been emerging, with the identification of potential and coordinated roles in gene silencing. Direct links between DNA methylation and repressive histone modifications play essential and coordinated roles in gene silencing. The idea that chromatin inactivation lies upstream of DNA methylation has been proposed previously, although the molecular mechanism by which these events are directly linked has remained elusive. Studies of the epigenetic inactivation of several tumor suppressor genes have demonstrated that methylation of histone H3K9 corresponds to gene inactivation, and precedes DNA methylation.29 Similarly, silencing of the human fetal globin genes has been shown to precede DNA methylation in somatic cell hybrids.31 Our studies with PRMT5-kd, PRMT5A-f and SUV4-20h1-kd cells suggest that establishment of repressive epigenetic modifications are coordinated, with the H4R3me2s and H4K20me3 marks functioning as necessary triggers for subsequent DNA methylation.

Discussion

DNA methylation and repressive histone modifications play essential and coordinated roles in gene silencing. Direct links between these processes have been emerging, with the identification of interactions between lysine methyltransferases, and DNA methyltransferases, methyl-CpG binding proteins and methyl-CpG enriched regions. We have recently shown that histone methylation and DNA methylation are directly linked in the context of human γ-globin gene silencing by the protein arginine methyltransferase PRMT5, which induces the repressive histone H4R3me2s mark that acts as a template for direct binding of DNMT3A.8 We now report that PRMT5-mediated γ-gene silencing is also dependent on the assembly of a multiple repressor complex containing previously unrecognised partners of PRMT5, including CK2α, and SUV4-20h1, in addition to DNMT3A, and components of the NuRD and Sin3 complexes. The enzymatic activity of PRMT5 is essential for assembly of this complex at the γ-promoter, as it is not observed in cells expressing a PRMT5 mutant lacking methyltransferase activity, despite the mutant retaining the ability to localize to the γ-promoter.

Figure 5. SUV4-20h1 induced epigenetic modification of the γ-globin genes is developmentally specific. (A) Quantitative reverse-transcriptase (Q-RT)–PCR analysis of γ-, β-, and α-globin gene expression in cord blood (CB) and bone marrow (BM). (B) H4K20me3 at the γ-promoter was measured by ChIP in chromatin fractions from erythroid progenitors from CB and BM. (C) Localization of H4K20me3 across the β-globin locus measured by ChIP in chromatin fractions from erythroid progenitors from BM. The precipitated DNA was amplified with primers specific for the indicated regions of the β-globin locus. methylation. This is supported by our finding of the H4K20me3 mark at the β-promoter in adult BM in levels above background, but with no enrichment for H4R3me2s, and no gene silencing. Conceivably, SUV4-20h1 could play a dual role, analogous to the methyltransferase G9a, involved in repression of the γ-globin gene with the PRMT5 complex, and activation of the β-globin gene with alternate partners. γ-globin gene expression is not detectable in a large proportion of uninduced K562 cells, indicating that the γ-genes are significantly repressed in these cells. This repression is due, in part, to DNA methylation as γ-gene induction is observed with 5-azacytidine, coincident with DNA hypomethylation. It is also due to other repressive epigenetic marks (H4R3me2s, H4K20me3, H3K9me3, H3K27me3) that can be erased with knockdown of components of the PRMT5 complex. Our findings suggest that γ-gene repression (like gene repression at most loci) is multilayered, requiring coordinated histone and DNA modifications.

Methylation of the CpG dinucleotides flanking the CAP site is essential for γ-gene silencing, and 2 of these CpGs reside within the region of the γ-promoter where the repressor complex assembles. Although the changes in methylation that we observed in our mutant K562 lines were modest compared with the increase in γ-gene expression, this is consistent with in vivo data in the baboon in which relatively modest changes in methylation induced substantial changes in γ-gene expression. DNMT3A-induced methylation of the γ-gene CpGs could serve as a template for the subsequent recruitment of MBD2 and MBD3, and this could be facilitated further by a direct interaction between the RG-rich N-terminus of MBD2 and PRMT5. MBD2 has recently been implicated in silencing of the human γ-genes in transgenic mice, although in this setting it was not localized to the γ-promoter. MBD2 has also been linked to silencing of the chicken embryonic genes, where it binds in a repressor complex containing NuRD components. The identification of both MBD2 and MBD3 in the γ-globin gene PRMT5-dependent repressor complex is in contrast to the PRMT5-containing complex that assembles on the P14ARF and P16INK4a CpG islands, which contains only MBD2. Unlike our findings, recruitment of PRMT5 in that context is dependent on DNA methylation, although a direct link between histone and DNA methyltransferases was not established.

The identification of the epigenetic markers H4S1ph and H4K20me3 at the γ-genes in the context of PRMT5-mediated transcriptional silencing expands the known roles of these histone modifications. To date, phosphorylation of H4S1 has been most widely studied in yeast, where it has been shown to regulate chromatin compaction during sporulation, a function that may be conserved in spermatogenesis in higher organisms. Further yeast studies have demonstrated that CK2α can induce this modification in the setting of transcriptional repression, and DNA repair. H4S1ph has been shown to oppose acetylation of histone H4 at lysines 5, 8, 12, and 16 by the NuA4 acetyltransferase complex, an effect that was abrogated by the methylation of H4R3. We noted a reduction in acetylation of H4K12 and K8 (but not K5 or K16) in the context of γ-gene silencing that was not blocked by the H4R3me2s mark, suggesting that H4S1ph at the γ-globin promoter may impede the function of another histone acetyltransferase complex. Yeast proteomic studies have found CK2 associated with Sin3 and mirroring their association with PRMT5 in our studies.

Tri-methylation of H4K20 has been studied in Drosophila and mammalian systems, where it has emerged as a hallmark of pericentric heterochromatin in concert with tri-methylation of H3K9 and H3K27. Induction of H4K20me3 in mammals is dependent on SUV4-20h1 isoforms, 2 SET domain HMTases that are recruited to the nucleosome through a direct interaction with HP1 isoforms. More recently, these 3 markers have been linked to transcriptional silencing of Hox genes, being enriched in the promotor and coding regions of the Ultrabithorax gene in the “off” state. The presence of SUV4-20h1 in the PRMT5 complex provides a direct mechanism by which this mark could be established at the γ-promoter. Interestingly, we did not identify SUV39h1 or HP1 in association with PRMT5, suggesting that recruitment of SUV4-20h1 in this setting may occur through a different mechanism to that observed at pericentric heterochromatin.

In addition to increased levels of the H4K20me3 mark at the γ-promoter, we also observed substantial enrichment of this mark at several of the LCR HSs, raising the possibility that coordinated repressive marks established synchronously at the promoters, and HSs could inhibit the LCR/globin gene interactions. Alternatively, the complex could assemble on the LCR and spread across the locus, similar to epigenetic modifiers acting at a distance in the β-globin cluster in the setting of activation of β-gene expression. Although the peak enrichment at the LCR occurred at HS3, the site at which the H4R3me2s modification also peaks in BM, high levels of the H4K20me3 mark were also observed at HS4 and HS2, which exhibit no enrichment of H4R3me2s. Similarly, higher levels of the H4K20me3 mark were detected elsewhere in the locus compared with the IgG control, and the significance of this is currently unclear.

The increased γ-gene expression in both cell lines and erythroid progenitors from BM suggests that the effects of the SUV4-20h1-kd are specific and direct. In keeping with this, we observed reduced PRMT5 localization, reduced levels of the H4R3me2s mark and loss of DNA methylation at the γ-gene in these cells. Activation of γ-gene expression in patients with β-thalassemia and sickle cell disease has been a therapeutic goal for many years. The identification of both PRMT5 and SUV4-20h1 as key regulators of γ-gene silencing provides novel targets for small molecule inhibitors, a strategy that we are actively pursuing.

Acknowledgments

We thank Sidney Pestka for the PRMT5Δ plasmid, Richard Gaynor for the PRMT5 plasmid, and members of the Jane laboratory for helpful discussions. Human BM and CB were collected after approval by the Melbourne Health, and Royal Women’s Hospital Human Research Ethics Committees.
