The establishment of the HSC pool in vertebrates depends not only on the formation and the propagation of these stem cells but also on their proper trafficking among the defined hematopoietic organs. However, the physiologic mechanisms that regulate HSC mobilization remain elusive. Through analysis of the zebrafish cmyb mutant cmybhkh3, we show that the suppression of cMyb function abrogates larval and adult hematopoiesis, with concomitant accumulation of hematopoietic stem/progenitor cells (HSPCs) in their birthplace, the ventral wall of the dorsal aorta (VDA). Cell tracking and time-lapse recording reveal that the accumulation of HSPCs in cmybhkh3 mutants is caused by the impairment of HSPC egression from the VDA. Further analysis demonstrates that the HSPC migratory defects in cmybhkh3 mutants are at least partly because of adversely elevated levels of chemokine stromal cell-derived factor 1a (Sdf1a). Our study reveals that cMyb plays a hitherto unidentified role in dictating physiologic HSPC migration by modulating Sdf1a signaling. (Blood. 2011;118(15):4093-4101)

Introduction

In vertebrates, hematopoiesis is a dynamic process that occurs in several successive waves.1-2 In mice, the primitive wave is initiated in the extraembryonic yolk sac and mainly generates embryonic erythrocytes and macrophages. This is followed by the definitive wave, which can continuously give rise to all blood lineages during fetal life and adulthood.1-2 Sustained multilineage blood production through definitive hematopoiesis relies on the existence of self-renewing common progenitors termed HSCs that reside in discrete anatomical sites during development.

It is now widely accepted that HSCs originate from the endothelium in the aorta-gonad-mesonephros (AGM) region,3-7 although the placenta8-9 and the yolk sac10 may also have the potential to form HSCs. These AGM-derived HSCs are believed to colonize the fetal liver (FL) and ultimately the BM,2,11 where they replicate and differentiate to replenish the supply of peripheral blood cells throughout fetal and adult life.1-2 This pathway is evolutionarily conserved from teleost fish to humans.11 In zebrafish, hematopoietic stem/progenitor cells (HSPCs) arise from the endothelium in the ventral wall of the dorsal aorta (VDA), a mammalian AGM counterpart, at around 30 hours post fertilization (hpf).4-5 Through in vivo fate mapping, these VDA-derived HSPCs have been shown to migrate to an intermediate hematopoietic compartment, the posterior blood island (PBI) or caudal hematopoietic tissue (CHT), before colonizing the kidney, the definitive hematopoietic organ in adult fish.12-15 Thus, the VDA, the CHT, and the kidney are the functional analogues of the mammalian AGM, FL, and BM, respectively. However, despite the delineation of the HSPC colonization pathway, the mechanisms that control HSPC mobilization from their birthplace to the downstream hematopoietic organs remain unclear.

The transcription factor cMyb was initially identified as a proto-oncogene associated with the development of avian leukemia.16 Studies on hematopoietic cell lines have shown that the expression of cMyb is largely restricted to HSCs and progenitor cells and is down-regulated on differentiation.17,18 Various cMyb mutant mouse alleles have been developed to investigate the physiologic functions of cMyb, and they have revealed that cMyb plays important roles in many hematopoietic pathways, including lymphoid development, HSPC maintenance, and HSPC differentiation.19-27 In particular, cMyb-null mice failed to develop fetal liver hematopoiesis and did not live past the embryonic stage. The cause generally ascribed to diminished fetal liver hematopoiesis in cMyb-null mice is impaired HSPC proliferation/differentiation in the absence of an intact cMyb gene.16 Recently, cmyb zebrafish and medaka mutants have been identified that display similar phenotypes: failure of definitive hematopoiesis in the larval and adult stages.28,29 However, it is unclear whether cMyb also plays an earlier role in regulating HSPC development in the AGM or the VDA in these animals.

In this article, we report a previously unknown function of cmyb in definitive hematopoiesis using a cmybkh3 zebrafish mutant line isolated from our N-ethyl-N-nitrosourea (ENU) mutant collection. This mutant harbors a splice mutation that results in the synthesis of a truncated cMyb protein lacking its transactivation domain.30 In cmybkh3 mutants, definitive hematopoiesis is initiated normally in the VDA but is compromised in the larval and the adult hematopoietic organs. Unexpectedly, we found that excessive HSPCs accumulated in the VDA of...
**Methods**

**Fish line**

Zebrafish were raised as described previously. The following fish strains were used in this study: AB, WIK, Tg(cd41:eGFP), Tg(gata1:DsRed), and Tg(jk1:eGFP).

**Laser-activated cell labeling**

Lineage tracking was performed as described previously. Briefly, the DMNB caged-Flu alone or along with morpholinio was injected into 1-cell-stage embryos from cmybhkrz3/Tg(cd41:eGFP) intercrosses. Subsequently, cells—irrespective of Cd41-eGFP expression—along the aortic floor were uncaged through focusing and confining 405-nm laser excitation to a defined segment of the aortic floor.

**WISH**

Antisense digoxigenin (DIG)-labeled RNA probes were generated by in vitro transcription and whole-mount in situ hybridization (WISH) was performed according to “the zebrafish book.”

**Double staining for cmyb or sdf1a RNA and eGFP protein**

To detect cmyb or sdf1a RNA and eGFP protein simultaneously, RNA was first developed with cy3-tyramide and protein was subsequently detected using Abs as described.

**IHC analysis**

The procedure for double Ab staining using eGFP/Flu and eGFP/αE1-globin has been described previously. For eGFP and DsRed containing, embryos were incubated with goat-anti-eGFP Ab (abcam) and rabbit-anti-DsRed Ab (clontech) and visualized using Alexa Fluor 488 donkey anti–goat and Alexa Fluor 555 donkey anti–rabbit (Invitrogen), respectively.

**Morpholinio injection**

For knockdown experiments, 1-cell-stage embryos were injected with 2 nL of sdf1a morpholinio (5'-CTACTACGATCCTTTGAGATCCAT-3') at a concentration of 1mM as reported.

**Cell proliferation assay**

Embryos at 54 hpf were incubated in 10mM BsdU (Sigma-Aldrich) for 2 hours and fixed for IHC as described with minor modifications. The embryos were stained with mouse-anti-BrdU (Roche) and goat-anti-eGFP Abs (Abcam), followed by Alexa Fluor 555 anti–mouse (Invitrogen) and Alexa 488 anti–goat (Invitrogen) for fluorescent visualization.

**Cell sorting and live cell-cycle analysis**

For cell sorting, cmybhkrz3/Tg(cd41:eGFP) mutant embryos were separated from their siblings under an epifluorescence microscope based on the fact that there was marked accumulation of CD41-eGFP+ cells in the VDA of mutants. Cell suspensions were prepared from the trunk tissue dissected from ~200 cmybhkrz3/Tg(cd41:eGFP) embryos or siblings as described. Other tissues were collected for confirmation by genotyping. Genotyping was done by sequencing the PCR-amplified DNA fragment using the following genotyping primers: 5'-TTGCACCTTATCACACCACA-3'/'5'—GGGAAGAACTCAAGTGAAAGG-3'. FACS and live cell cycle analysis were performed as described. For sorting, a 70-μm nozzle was used for allowing cells to pass through in a FACS Aria II flow cytometer (Becton Dickinson). For detecting Hoechst and eGFP signal, near UV laser and 488nm laser were used, respectively.

**Quantitative RT-PCR**

Total RNA from sorted cells and embryos was extracted using the RNeasy Kit (QUIAGEN). For CDNA preparation from the total RNA of embryos, RT was performed using Omniscript RT Kit (QUIAGEN). For specific detection of cmyb WT or hkrz3 aberrant splicing form, the following primer sets were used: the common forward primer is 5'-CACTGCTGCTATCCAGAGA-CACTAC-3' (814_FP), and the reverse primers are 5'-AGCCGTTCTATG-GAGATTGTGAT-3' (947_wt_RT) and 5'-CATGGAGACTGGTGTTTGG-3' (947_hkrz3_RT) specific for cmyb WT form and hkrz3 aberrant splicing form, respectively. The primer set for indiscriminately detecting both cmyb forms is 5'-CACGAGAAACTCAGAAGACGACT-3'/5'-GCTTGTTGTGTGATGTAGTGC-3' (575_FP/782_wt_RT). For preparation of cDNA from total RNA of sorted cells, SuperScript III first-strand synthesis system (Invitrogen) was used. Primers of β-actin and hematopoietic and endothelium markers were described, whereas the primer set of sdf1a was mCherry or mCherry alone were mounted with 3% methyl cellulose for imaging.

**Gene screening and positional cloning**

ENU mutagenesis was carried out as described previously. cmybhkrz3 mutant was identified because of its complete absence of lysozyme C (lyz) expression. Linkage scanning was done with bulkly segregation analysis guided by the Zon laboratory’s positional cloning instruction (http://zon.chlab.org/). Intermediate resolution mapping with 39 embryos localized cmybhkrz3 mutation 23.08cm south to z0039 and 1.28cm north to z5141 on linkage group 23. cmyb gene was mapped to this genetic interval. Mutation in cmyb genomic locus was identified through sequencing.

**Transactivation assay**

To construct the yeast expression vectors for the GAL4 fusion proteins, the wild-type and hkrz3 mutated cMxb TAD fragments were cloned into the 2 hybrid bait plasmid pGBK7 (Clontech). The yeast strain AH109 (Clontech) was used for the yeast growth inhibition experiment.

**Establishment of the Tg(hsp70:Myc-cMyb) line and rescue of cmybhkrz3 mutants**

For generation of the Tg(hsp70:myn-cMx) transgenic line, zebrafish heat shock protein (hsp) 70 promoter driving the Myc-tagged cmyb was inserted into pTol vector with minimal Tol2 elements and a SV40 polyA sequence. One-cell stage cmybhkrz3/Tg(cd41:eGFP) embryos were injected with this construct together with Tol2 transposase mRNA and raised to adult. The founder fish was identified by PCR. The stable F1 Tg(hsp70:myn-cMx) embryos were obtained by mating founder fish with AB and confirmed by anti-Myc immunostaining. For Myc-cMx Ab staining, 35 hpf Tg(hsp70: myc-cMx) embryos were heat-shocked at 40°C for 1 hour and recovered at 28°C for 2 hours before fixed for anti-Myc Ab staining. For cMx embryo rescue, cmybhkrz3/Tg(cd41:eGFP)/Tg(hsp70:myn-cMx) embryos and siblings were heat-shocked at 40°C at 28, 35, and 48 hpf for 1 hour and fixed at 53 hpf for anti-eGFP staining to detect Cd41-eGFP+ cells.
**Sdf1a transient overexpression experiment**

For transient overexpression of sdf1a, 1-cell-stage Tg(cd41:eGFP) embryos were injected with CMV:sdf1a construct together with CMV:mcCherry construct which expressed Sdf1a and mcCherry from a constitutively active CMV promoter. Embryos injected with CMV:mcCherry were used as negative controls.

**Statistical analysis**

Statistical evaluation was performed by using the 2-tailed t test. Differences were considered significant if the P value was < .05.

---

**Results**

**Failure of larval and adult definitive hematopoiesis in the cmyb\textsuperscript{hkz3} zebrafish mutant line.**

To investigate the molecular basis of HSPC formation, trafficking, maintenance, and differentiation, we took advantage of a zebrafish cmyb mutant line (cmyb\textsuperscript{hkz3}) isolated from our ENU mutant collection. The CMYB\textsuperscript{hkz3} mutant harbors a splice mutation (supplemental Figure 1A-B, available on the Blood Web site; see the Supplemental Materials link at the top of the online article) that leads to the synthesis of a truncated CMyb protein lacking its transactivation domain (supplemental Figure 1C).\textsuperscript{30} As the wild-type (WT) CMYB transcript was not detected in cmyb\textsuperscript{hkz3} mutants (supplemental Figure 2A) and the truncated CMyb\textsuperscript{hkz3} protein was inactive in a yeast transactivation assay (supplemental Figure 2B), we believe that cmyb\textsuperscript{hkz3} is a loss-of-function mutation. To characterize the effects of the cmyb\textsuperscript{hkz3} mutation on definitive hematopoiesis, we examined the expression of a panel of HSPC and lineage-specific markers in cmyb\textsuperscript{hkz3} mutant embryos at 4-5 dpf, when definitive hematopoiesis is normally well under way in the CHT, thymus, and pronephros.\textsuperscript{41} In siblings, strong cmyb expression, indicative of HSPCs, was found in the CHT, thymus, and pronephros (supplemental Figure 3A,C). However, in cmyb\textsuperscript{hkz3} mutants, cmyb expression decreased from 2 dpf onward (supplemental Figure 3E-F), and almost no cmyb signals were present at 4 dpf (supplemental Figure 3B,D). In the same time window, the expression of another HSPC marker, Cd41-eGFP,\textsuperscript{40} also decreased in the CHT of cmyb\textsuperscript{hkz3} mutants (supplemental Figure 3G-H). Expression of the lymphoid marker rag1 was absent in the developing thymus (supplemental Figure 3I), and the populations of definitive erythroid and myeloid cells, represented by ael-globin\textsuperscript{41} and mpx\textsuperscript{41} RNA expression, respectively, were also profoundly decreased in cmyb\textsuperscript{hkz3} mutants (supplemental Figure 3J,K). These results demonstrate that, as in cmyb-null mice,\textsuperscript{10} and the cmyb\textsuperscript{23/27} zebrafish mutant,\textsuperscript{29} the cmyb\textsuperscript{hkz3} mutation compromises the development of multiple blood cell lineages in definitive hematopoiesis. Presumably as a result of this large-scale failure of definitive hematopoiesis, cmyb\textsuperscript{hkz3} mutants were unable to survive to adulthood, most died around 10 dpf.

The overall phenotypic resemblance between cmyb\textsuperscript{hkz3} mutants and CMyb null mice suggests that they share common underlying cellular defects. In light of the impaired HSPC proliferation observed in the fetal liver of CMyb null mice,\textsuperscript{16} we speculated that HSPC proliferation in the CHT of cmyb\textsuperscript{hkz3} mutants may also be hindered. To test this, we performed a BrdU incorporation assay in which cmyb\textsuperscript{hkz3}/Tg(cd41:eGFP) mutant embryos were pulse-labeled using BrdU at 54 hpf and then stained for eGFP and BrdU. Quantification of the eGFP/BrdU double-positive cell population in mutants and siblings showed that a decreased proportion of Cd41-eGFP\textsuperscript{+} HSPCs in the CHT region of mutants incorporated BrdU (supplemental Figure 4A), suggesting that HSPC proliferation is attenuated in the CHT region of cmyb\textsuperscript{hkz3} mutants. Living cell-cycle analysis using Hoechst 33 342 staining further confirmed that the proliferation of Cd41-eGFP\textsuperscript{+} precursors in 3-dpf cmyb\textsuperscript{hkz3} mutants was reduced, with a decreased proportion of cells in the S phase of the cell cycle (supplemental Figure 4B). Thus, akin to the CMyb null mutation in mice, the cmyb\textsuperscript{hkz3} mutation interrupts definitive hematopoiesis partly by impairing HSPCs proliferation in the CHT.

**Accumulation of HSPCs in the VDA region of cmyb\textsuperscript{hkz3} mutants**

To investigate whether there are any earlier hematopoietic defects in cmyb\textsuperscript{hkz3} mutants, we examined HSPC development in the VDA, where they are formed. Cd41 has recently been shown to be one of the earliest surface markers expressed by nascent HSPCs, appearing shortly after their emergence in the VDA.\textsuperscript{40} Therefore, the cmyb\textsuperscript{hkz3}/Tg(cd41:eGFP) transgenic line was used for the analysis of HSPC development in the VDA. Surprisingly, we found that cmyb\textsuperscript{hkz3} mutant embryos had far more Cd41-eGFP positive (Cd41-eGFP\textsuperscript{+}) cells in their VDA than siblings from 2 dpf onward (Figure 1A, supplemental Figure 5A). The number of cells expressing cmyb, another HSPC marker, was similarly increased in the VDA of cmyb\textsuperscript{hkz3} mutants, and double staining with endogenous cmyb RNA and Cd41-eGFP showed that the majority of Cd41-eGFP\textsuperscript{+} cells also stained positive for cmyb (Figure 1A, supplemental Figure 5B). Quantification analysis showed that cmyb\textsuperscript{hkz3} mutant embryos contained approximately twice as many cmyb/ Cd41-eGFP\textsuperscript{+} cells as their siblings from 2 dpf onward (Figure 1B). Quantitative PCR analysis further showed that runx1 and other endothelial and HSPC markers were also increased in cmyb\textsuperscript{hkz3} embryos (Figure 1C). These results demonstrate that in cmyb\textsuperscript{hkz3} mutants, cells positive for HSPC markers accumulate in the VDA after the offset at which definitive hematopoiesis normally begins. It is unlikely that the excess of HSPCs in the VDA is caused by the malformation of the vascular system, because double staining using eEl-globin protein and Flk1-eGFP showed intact vasculature containing well-circulating erythrocytes in cmyb\textsuperscript{hkz3} mutants (supplemental Figure 5C). The accumulation of Cd41-eGFP\textsuperscript{+} cells can be reverted by reintroduction of WT cmyb expression, further demonstrating that this phenotype is caused by the loss of cmyb function (supplemental Figure 6).

To confirm that the Cd41-eGFP\textsuperscript{+} cells accumulated in the VDA of cmyb\textsuperscript{hkz3} mutants are HSPCs, not differentiated cells committed to downstream lineages, we tested whether there was a concomitant increase in the differentiated lineage markers gata1 and mpx, indicative of erythroid and myeloid cells, respectively, in the VDA of cmyb\textsuperscript{hkz3} mutants. Imaging of 52 hpf cmyb\textsuperscript{hkz3}/Tg(gata1:DsRed)/Tg(cd41:eGFP) mutant embryos and their siblings revealed that gata1-DsRed–positive cells did not accumulate as Cd41-eGFP\textsuperscript{+} cells did in mutant embryos (supplemental Figure 7A). Similarly, no obvious increase in myeloid cell populations was found in the cmyb\textsuperscript{hkz3} mutant VDA as shown by the normal mpx staining (supplemental Figure 7B). Taken together, the increased expression of HSPC markers but not differentiated lineage markers strongly indicates that the Cd41-eGFP\textsuperscript{+} cells accumulated in the cmyb\textsuperscript{hkz3} mutant VDA are HSPCs. This was further supported by video-enhanced differential interference contrast (DIC) imaging analysis,\textsuperscript{32} which showed that the accumulated Cd41-eGFP\textsuperscript{+} cells in cmyb\textsuperscript{hkz3} mutant embryos had large nuclei and little cytoplasm, morphologic features identical to those of HSPCs described previously (supplemental Figure 7C).\textsuperscript{30}
The accumulation of HSPCs in \textit{cmyb}^{hkz3} mutants is because of the impairment of HSPC egression from the VDA

In principle, HSPC accumulation in the VDA of \textit{cmyb}^{hkz3} mutants could result from any one or more of the 3 following underlying cellular abnormalities: (1) augmented de novo HSPC genesis in the VDA; (2) enhanced proliferation of existing VDA HSPCs; (3) impaired HSPC egression from the VDA. To determine whether HSPCs are generated in excess in \textit{cmyb}^{hkz3} mutant embryos, we monitored the expression of the early HSPC marker \textit{runx1} at 30 hpf, when HSPCs are normally transiting from the endothelium and no HSPCs are released from the VDA into circulation.\textsuperscript{13,14,40} The results showed that neither the number of \textit{runx1} \textsuperscript{*} cells nor the per-cell expression level of \textit{runx1} was changed in \textit{cmyb}^{hkz3} mutants, indicating that the hemogenic aortic endothelial cells competent to transform into HSPCs are formed normally in \textit{cmyb}^{hkz3} mutants (Figure 2A-B).

We next investigated the proliferation of the accumulated VDA \textit{Cd41-eGFP} \textsuperscript{*} cells in \textit{cmyb}^{hkz3} mutants using a BrdU pulse-labeling experiment (Figure 2C). Quantification of the \textit{Cd41-eGFP}/BrdU double positive cell population showed that \textit{Cd41-eGFP} \textsuperscript{*} HSPCs in the VDA of \textit{cmyb}^{hkz3} mutants and siblings incorporated BrdU comparably (Figure 2D), indicating that HSPC proliferation in the VDA is not affected by \textit{cmyb}^{hkz3} mutation.

The above observations suggest that the accumulation of HSPCs in \textit{cmyb}^{hkz3} mutants is caused by the impairment of HSPC egression from the VDA. To prove that HSPC migration is defective in \textit{cmyb}^{hkz3} mutants, we tracked the migration of HSPCs from the VDA to the CHT using a photoactivatable tracer, DMNB-caged fluorescein (Flu).\textsuperscript{15} In this assay, cells in the aortic floor were labeled at 30 hpf by exposing embryos injected with DMNB-caged Flu to a 405-nm laser pulse and \textit{Cd41-eGFP}/Flu double-positive cells in the CHT were scored 16 hours later (Figure 2A-B).
Figure 3. VDA-derived Cd41-eGFP+ HSPCs are impaired in populating the CHT in cmyb<sup>h<sub>kz3</sub></sup> mutants. (A) The cmyb<sup>h<sub>kz3</sub></sup>/Tg(cd41:eGFP) embryos were injected with DMNB-caged Flu at 1-cell stage. The aortic floor, where Cd41-eGFP<sup>+</sup> HSPCs will later derive, was labeled by exposure to a pulse flash of UV at 30 hpf. (B) Emergence of eGFP/Flu double-positive cells (right panel, white arrows indicated) were scored and quantified in the CHT 16 hours after UV exposure (left panel). Representative figure was shown in the right panel (eGFP, green; uncaged-Flu, red). Units on the y-axis represent the average number of eGFP/Flu double-positive cells (n = 9, mean ± SD). An asterisk indicates significant difference with sibling (t-test, P < .05).

Figure 4. Accumulation of Cd41-eGFP<sup>+</sup> HSPCs in cmyb<sup>h<sub>kz3</sub></sup> mutants results from crippled egress of HSPCs from the VDA. (A-B) Still image sequence extracted from confocal microscopic recording of red boxed VDA area in cmyb<sup>h<sub>kz3</sub></sup> mutant embryo (B) and sibling (A) between 50 and 60 hpf in each time points indicated above each panel. A, aorta; V, vein. (C) A corresponding recording period. Numbered HSPCs (yellow arrows) were released into circulation at time points indicated above each panel. A, aorta; V, vein. (D) A corresponding summary of the sequence of cells exiting from the VDA in sibling (A) and cmyb<sup>h<sub>kz3</sub></sup> mutant (B). (D) Quantification of the numbers of Cd41-eGFP<sup>+</sup> HSPCs exiting from the VDA in a 5-hour recording period in 2- to 2.5-hpf embryos (n = 5, mean ± SD). An asterisk indicates significant difference with wild type (t-test, P < .05).
from VDA is roughly in agreement with the uncaging result, which estimated a 2-fold reduction in the number of VDA-derived HSPCs colonizing the CHT in cmyb

mutant embryos (Figure 3B, supplemental Figure 8, and Figure 4D). Together, photoactivated cell tracing and live imaging analysis demonstrate that impaired HSPC migration is one of the major reasons for the accumulation of HSPCs in the VDA of cmyb

mutants, and that this accounts at least in part for the diminished larval hematopoiesis observed in the secondary hematopoietic organs of these embryos.

The cMyb-Sdf1a axis plays an essential role in the regulation of HSPC migration

Chemokine signaling has been shown to be an important pathway for directing cell migrations, such as primordial germ cell migration, during embryogenesis and HSPCs mobilization in adulthood. In particular, several studies in mammals have indicated that the down-regulation of the chemokine stromal cell-derived factor 1 (SDF1), which is normally constitutively expressed in the BM and cells such as CD34+ progenitor cells, is tightly associated with G-CSF–induced HSC mobilization from the BM into the peripheral blood. Therefore, we postulated that chemokine signaling may play a role in cMyb-mediated HSPC egression from the VDA. To test this possibility, we examined the expression of several key molecules involved in chemokine signaling in cmyb

mutants and siblings. We found that, in 53-hpf WT embryos, sdf1a transcripts were faintly detected and were costained with the majority of Cd41-eGFP+ cells (Figure 5A). Notably, in cmyb

mutants, sdf1a expression was found to be moderately up-regulated in VDA Cd41-eGFP+ cells. Consistently, RT-PCR analysis of Cd41-eGFP+ cells sorted from the dissected trunk regions of 2-dpf embryos showed that sdf1a expression was markedly increased in cmyb

mutants compared with siblings (Figure 5B). As high concentrations of sdf1a have been documented to act as a retention signal for HSCs in the BM of mice, we reasoned that the abnormally high levels of Sdf1a in cmyb

mutants may trap HSPCs in the VDA. To test this hypothesis, 2 assays were carried out. We first reduced Sdf1a levels using antisense morpholino (MO) knockdown to see whether this could rescue the migratory defects of HSPCs in cmyb

mutants. Photoactivated cell tracing analysis showed that in cmyb

mutants receiving sdf1a-MO, the number of VDA-born HSPCs seeding the CHT increased 26% compared with embryos receiving control MO (Figure 5C). No obvious difference was seen in control siblings injected with sdf1a-MO and control MO (Figure 5C). We then assayed whether ectopically elevating Sdf1a level in HSPCs in WT embryos was sufficient to trap HSPCs in the VDA. This was achieved by comparing the emigration of Cd41-eGFP+ HSPCs from the VDA of embryos mosaicly overexpressing Sdf1a plus mCherry and mCherry alone. Live imaging revealed that Cd41-eGFP+ HSPCs with Sdf1a ectopic expression tend to remain in the VDA for longer periods of time compared with Cd41-eGFP+ HSPCs in the same embryos without Sdf1a overexpression and those with only mCherry overexpression (Figure 6A-B; supplemental Videos 3-4). Quantitatively, only 27% of Cd41-eGFP/mCherry double-positive HSPCs in Sdf1a overexpressed embryos exited the VDA region within 9 hours, whereas 57% of these cells in control embryos did within the same recording period (Figure 6C). Taken together, these data demonstrate that the defective egression of HSPCs from the VDA in cmyb

mutants is at least partly because of the adverse elevation of Sdf1a expression in HSPCs, indicating that cMyb-mediated attenuation of sdf1a expression is required for HSPC release from the VDA.
Discussion

In this study, we isolated a novel cmyb zebrafish mutant allele, cmyb/bkz, which failed to undergo definitive hematopoiesis in the CHT, kidney, and thymus, akin to the phenotypes of cMyb-null mice and zebrafish cmyb22-27,16,29. Strikingly, we observed that HSPCs in cmyb/bkz mutants accumulated in their birthplace, the VDA, as a result of the diminished egress of HSPCs from the VDA to the CHT. Thus, the migratory defects of HSPCs are likely to be the earliest factor leading to the failure of fetal/larval and adult hematopoiesis in cMyb-deficient animals. Beyond 2 dpf in the CHT, the gradual reduction of the expression of cmyb and Cd41-eGFP, 2 definitive HSPC markers, could be observed more and more clearly. However, cmyb expression decreased more dramatically in the CHT at 4 dpf than Cd41-eGFP expression. As thrombocytes display high Cd41-eGFP expression40 and the CHT-born erythromyeloid progenitors (EMP)s40 also expressed Cd41-eGFP, the residual Cd41-eGFP expression in the CHT of mutants might reflect the presence of circulating thrombocytes and EMP or EMP-derived cells that were preserved in cmyb/bkz mutants. Nonetheless, tracing the VDA-derived Cd41-eGFP+ cells in cmyb/bkz mutants during the normal time window of HSPC migration, demonstrating a bona fide role of cmyb in controlling HSPC migration.

Notably, while cmyb/bkz mutants show only a 2-fold reduction in HSPC migration from the VDA to the CHT, the reduction in the populations of further differentiated blood cells in the CHT, kidney, and thymus past 4 dpf is much more profound. This is likely because of the proliferation defect of mutant HSPCs in these subsequent hematopoietic compartments shown by cell-cycle and cell-tracking analysis, which is consistent with the observation in c-Myb null mice.19 As cMyb is also known to be required for T-cell development in mice23; the complete absence of thymic rag1 expression in cmyb/bkz mutants might be caused by a combination of reduction of definitive hematopoietic precursors and blockage of T-cell development. Thus, we believe that the profound decrease in multilineage hematopoiesis in definitive organs likely reflects the disruption of the functions of cmyb in multiple aspects of hematopoietic development. Through analysis of the cmyb/bkz mutant, our study reveals that cMyb plays a role in regulating the exit of HSPCs from their birthplace, the VDA, for the colonization of the larval hematopoietic organ, the CHT, a function which has not been found in previous studies of cMyb-deficient models. To our knowledge, cMyb is the first clue to the molecular control of the earliest step of the developmental trafficking of HSPCs during ontogeny. However, the question of whether cmyb also regulates HSPC intravasation from the CHT remains unclear, and this would be an interesting topic for future study.

Mechanistically, we show that the cMyb-regulated HSPC mobilization is mediated at least in part by suppressing the expression of sdf1a, a chemokine molecule in HSPCs. In this model, nascent HSPCs should express a relatively high level of sdf1a, which serves as a brake to prevent the precocious release of HSPCs from the VDA. As HSPCs mature, sdf1a expression in HSPCs is down-regulated by cMyb, and this facilitates HSPC release from the VDA. This is consistent with previous observations in mice showing that the down-regulation of SDF1 is tightly associated with G-CSF–induced HSPC mobilization from the BM into the peripheral blood.45 Notably, in mammals, SDF-1 is constitutively expressed by stromal cells in the BM and CD34+ progenitor cells.44 Our study shows that Sdf1a expressed by HSPCs contributes to the regulation of HSPC mobilization from the VDA to the CHT. However, the contribution of relevant stromal cells to local Sdf1a levels in the VDA and to HSPC mobilization remains unexplored because of lack of knowledge of stromal elements in the VDA region. The question of whether sdf1a is a direct or indirect target of cMyb is currently unclear and requires future study.

The SDF1-CXCR4 axis plays a role in HSC migration in mammals.47 We have attempted to address the involvement of candidate sdf1a receptors, cxc4a and cxc4b, in mediating cMyb regulated HSPC mobilization. However, unlike sdf1a expression, which is up-regulated, the expression of cxc4a/c4b is unaffected in the HSPCs of cmyb/bkz mutants (data not shown), suggesting that cmyb may control the expression of the ligand rather than the receptor to modulate chemokine signaling. However, the administration of CXCR4 antagonist AMD310049 failed to rescue the HSPC mobilization defects in cmyb/bkz mutants (data not shown), a result that could be because of either inefficient penetration and targeting of the compound or the fact that Sdf1a uses different receptors in the VDA. Thus, cognate receptors and downstream transducers that mediate Sdf1a signaling in the context of HSPC mobilization from the VDA to the CHT remain to be identified and characterized in future studies.
The characterization of cMyb as a physiologic regulator of HSPC trafficking may have pathologic implications. It is known that aberrant cMyb activity is associated with the development of a variety of human cancers, including leukemia, lymphomas, colon carcinomas, and melanomas.50 presumably via up-regulating tumor cell growth.51 On the other hand, cancer stem cells also express the SDF1 receptor CXCR4 on their surfaces, and the SDF1-CXCR4 axis has been implicated in the direction of metastasis.52 Our new findings suggest that cancer cells may hijack the cMYB-SDF1 axis for their metastasis. In light of this, it may prove useful to investigate the role of cMYB and its interaction with the SDF1 chemokine signaling pathway in tumorigenesis.

Acknowledgments
The authors thank V. Korzh, R. Handlin, L. Zon, and P. Herbold for providing sdf1a probe, Tg(cdx1:EGFP), Tg(gata1:DsRed) transgenic fish, and DIC system advice, respectively. They thank Anthony Zhang for editing the manuscript.
