B-cell antigen receptor (BCR)–mediated signaling plays a critical role in chronic lymphocytic leukemia (CLL) pathogenesis and gives an in vitro survival advantage to B cells isolated from patients with unfavorable prognostic factors. In this study, we undertook to elucidate the signaling intermediates responsible for this biologic alteration. In responding cells only, in vitro BCR engagement triggers global phosphorylation of Syk, activation of phospholipase Cγ2, and intracellular calcium mobilization, reflecting competency of BCR signaling. The calcium–calcineurin-dependent transcription factor NFAT2 is up-regulated and to some extent constitutively activated in all CLL B cells. In contrast, its DNA-binding capacity is enhanced on IgM stimulation in responding cells only. NFAT inhibition using the VIVIT peptide prevents induction of CD23 target gene and IgM-induced survival, converting responding cells to unresponsive status. At the opposite, ionomycin-induced NFAT activity allows survival of nonresponding cells. These results demonstrate that the functional heterogeneity relies on variability of protein levels establishing BCR-dependent thresholds and NFAT-dependent activation. Finally, status of the BCR-NFAT pathway for each patient reveals its relevance for CLL clinical outcome and points out to BCR-NFAT intermediates as promising functional therapeutic targets.

Introduction

Despite encouraging scientific and therapeutic advances, chronic lymphocytic leukemia (CLL) disease remains incurable with standard therapy, prompting the need for the development of novel therapeutic agents. CLL affects predominantly elderly people and, based on clinical and biologic annotations, the course of the disease can be classified from indolent to more aggressive subtypes. CLL is defined as an expansion of monoclonal, slowly dividing CD5−/CD20− B cells. In contrast, its DNA-binding capacity is enhanced on IgM stimulation in responding cells only. NFAT inhibition using the VIVIT peptide prevents induction of CD23 target gene and IgM-induced survival, converting responding cells to unresponsive status. At the opposite, ionomycin-induced NFAT activity allows survival of nonresponding cells. These results demonstrate that the functional heterogeneity relies on variability of protein levels establishing BCR-dependent thresholds and NFAT-dependent activation. Finally, status of the BCR-NFAT pathway for each patient reveals its relevance for CLL clinical outcome and points out to BCR-NFAT intermediates as promising functional therapeutic targets.

Most CLL cells characteristically display lower levels of surface IgM and IgD compared with normal B cells. Low BCR surface expression is partly explained by an inefficient assembly, trafficking, or both of Igs that are noncovalently bound to CD79a and CD79b. The tyrosine kinase Syk has been shown to function downstream of the BCR complex in CLL B cells. Inhibition of Syk expression or activity induces apoptosis of CLL cells both in vitro and in vivo, suggesting a prosurvival role for the kinase. Zap70, the second member of the Syk family, is considered a surrogate marker for unmutated IGHV gene expression and probably facilitates BCR signaling in CLL cells independently from its tyrosine kinase activity. Effectors downstream of Syk include, among others, phospholipase Cγ2 (PLCγ2) that is responsible for mobilization of intracellular pools of calcium. In CLL B cells, BCR ligation induces heterogeneous responses in terms of PLCγ2 phosphorylation and intracellular calcium mobilization. In turn, sustained calcium uptake activates the serine and threonine phosphatase calcineurin. Once active, calcineurin promotes dephosphorylation and nuclear translocation of the nuclear factor of activated T cells (NFAT) family of transcription factors, which cooperate with other factors to promote transcriptional regulation of numerous survival genes in lymphocytes. Although nuclear NFAT1 may present as a hallmark of unstimulated CLL B cells, the molecular events that lead to activation of NFATs and cell survival remain to be determined.

Based on the heterogeneous response of CLL B cells in terms of in vitro cell survival on BCR ligation, we demonstrated previously that the responsiveness allows the distinction between 2 “responder” and “nonresponder” groups of patients. The responder group, characterized by cells with an elevated response in terms of transcriptional targets after sustained BCR stimulation, includes patients with unfavorable prognostic factors.6

We show in the present study that the levels of cell surface IgM and intracellular Syk, Zap70 proteins, or a combination mandate a critical threshold to promote BCR signaling in CLL B cells. Moreover, BCR competency is dependent on global phosphorylation of Syk but not Zap70, PLCγ2 activation, and intracellular Ca2+ mobilization in CLL B cells from the responder cases. Importantly, endogenous NFAT2 that is overexpressed and binds DNA in all unstimulated CLL B cells is further activated after sustained BCR stimulation in “responding” B cells only. Treatment of CLL B cells with the VIVIT peptide inhibitor antagonized the BCR-dependent stimulation of NFAT2 and blocked cell survival. The relevance of this activating pathway is demonstrated through measurement of progression-free survival (PFS) and overall survival (OS) in CLL patients. Together, our data show that targeting BCR-mediated pathways and its downstream intermediates may be a promising therapeutic approach in CLL.

Methods

CLL B-cell purification

After informed consent and in accordance with the Declaration of Helsinki, peripheral blood samples were obtained from patients fulfilling diagnostic and immunophenotypic criteria for CLL (supplemental Table 1, available on the Blood Web site; see the Supplemental Materials link at the top of the online article) at the Service d’Hématologie Biologique, Avicenne Hospital, Bobigny. B cells were purified by negative selection using RosetteSep Human B Cell Enrichment Cocktail (StemCell Technologies) following the manufacturer’s instructions, and purity was verified as described previously.6 Peripheral blood mononuclear cells (PBMCs) were isolated on density gradient and further analyzed either freshly or after viable thawing from liquid nitrogen storage in fetal bovine serum (FBS; PAA Laboratories) and 10% DMSO (Sigma-Aldrich). Jurkat cell lines were grown in RPMI 1640 (PAA Laboratories) and 10% FBS and 1% penicillin-streptomycin (PAA Laboratories). B cells were purified with a BD FACSCanto II analyzer and DIVA software (BD Biosciences), IgM/RPE (Dako), or relevant isotypic controls (BD Biosciences and Dako). In brief, fresh blood samples free of red blood cells, thawed PBMCs, or purified B cells were incubated in RPMI 1640 (PAA Laboratories) in the presence or not of soluble AffiniPure F(ab′)2 fragment goat anti-human IgM (10 μg/mL/107 cells; Southern Biotechnology) for 10 minutes. Cells were further labeled in 1 × phosphate-buffered saline (PBS) containing saturating concentrations of mAbs for 20 minutes, washed twice, and then analyzed immediately or further subjected to intracellular labeling.

Phosphorylation assay. Phosphorylated-Syk/Zap70 (Alexa Fluor 647 anti-pY352 Syk/Zap70 pY319) and -PLCγ2 (PE anti-pY759) as well as Syk and Zap70 (FITC-conjugated anti-Syk; BD Biosciences Pharmingen and R-PE anti-Zap70; Southern Biotechnology mAbs) were analyzed simultaneously using Lyse/Fix Buffer and Perm Buffer I (BD Biosciences), according to the manufacturer’s protocols. Data were acquired and analyzed with a BD FACSComp II analyzer and DIVA software (BD Biosciences).

Detection of intracellular calcium. One million CLL B cells were washed in Cell Loading Buffer (1 mM calcium, 1 mM magnesium, and 1% FBS) and incubated with 2 μM calcium indicator (fluor-4 AM; Invitrogen) for 30 minutes at 37°C in the dark. After further washing, cells were incubated in Cell Loading Buffer for 30 minutes at 37°C in the dark and finally analyzed by flow cytometry (BD FACSComp II and DIVA software) for 300 seconds (stimulation was performed with 10 μg of α-IgM/mL/107 cells at t = 60 seconds and 5 μM ionomycin at t = 290 seconds).

Immunofluorescence staining

Unstimulated or IgM-stimulated B cells were seeded on polylysine-coated coverslips for 30 minutes at 37°C and eventually stored at −20°C. Cells were fixed in PBS containing 4% paraformaldehyde for 10 minutes and permeabilized in PBS containing 1% Triton X-100 (Sigma-Aldrich) for 10 minutes. After incubation for 45 minutes in blocking solution (PBS and 5% skimmed milk), anti-NFAT2 Ab (1:500; Ozyme) was applied at room temperature for 1 hour. Coverslips were further washed in PBS and incubated with Alexa 488–coupled secondary Ab (1:1000; Invitrogen) for 1 hour at room temperature. Nuclei were counterstained with 4,6-diamidino-2-phenylindole (Sigma-Aldrich) before slide mounting with Mowiol (Sigma-Aldrich).

RT-PCR

Total RNAs from CLL patient or healthy donor B cells were purified (QIAGEN) and quantified by spectrophotometry. cDNAs were synthesized using SuperScript II Reverse Transcriptase (Invitrogen). Amplification was performed in triplicates using SYBR Green PCR Mastermix and the appropriate primers (supplemental Methods; 10 μM, Applied Biosystems) using a 7000 SDS thermal cycler (Applied Biosystems).

ELISA for NFAT2 DNA-binding activity

NFAT2 DNA-binding capacity was measured using TransAM NFATc1 kit (Active Motif) according to the manufacturer’s instructions (supplemental Methods).

Data analysis and statistics

Values are presented as mean ± SEM. Statistical significance was determined using the Mann-Whitney test as appropriate. P values of
less than .05 were considered statistically significant. A 2-tailed unpaired Student t test was used to compare individual groups. A level of $P$ less than .05 was considered significant. Statistical analyses were performed using GraphPad software. Distributions of PFS and OS were estimated by the Kaplan-Meier method. Log-rank test was performed to test the difference of survival between groups.

Results

BCR triggering with anti-IgM immobilized antibodies promotes a heterogeneous cell survival response that allowed us classifying CLL patients into 2 responder and nonresponder groups. Although responder CLL B cells exhibited increased metabolic activity, nonresponder cells showed no significant enhancement. Assessment of the metabolic activity of CLL cells on BCR stimulation (% MTS) on a cohort of 77 untreated CLL patients lead to their sorting into 2 subgroups: 37 nonresponder and 40 responder patients (supplemental Table 1).

We observed previously an elevated transcriptional response on BCR stimulation in CLL cells isolated from responder patients only. To dissect this functional heterogeneity between the 2 groups of patients, we examined whether B-cell survival might result from differential expression, activity, or localization of signaling effectors.

Membrane IgM, but not CD20 coreceptor, has higher levels of expression in responding B cells

Low levels of surface IgM are the hallmark of CLL B cells. We analyzed whether cell surface IgM levels might diverge between nonresponder and responder cases. Relative IgM surface expression was determined using flow cytometry on CD5+CD19+ B cells isolated from nonresponder (n = 20) and responder (n = 20) patients and compared with non-CLL B cells (control; n = 11). Despite the expected overall lower membrane expression in CLL B lymphocytes compared with control B cells, leukemic B cells from responder cases exhibited significantly higher IgM levels than those from nonresponder cases ($P = .0037$; Figure 1A and supplemental Figure 1A). In contrast, no significant difference was observed for the CD20 marker that participates to and modulates the BCR signaling complex, between nonresponder (n = 20) and responder (n = 20) groups (Figure 1B and supplemental Figure 1B). These results demonstrate a variation in the antigen-binding components of the complex, arguing for a critical level of signaling capacity in CLL B lymphocytes.

Syk and Zap70 levels of expression are higher in responding CLL B cells

On triggering, BCR complex-driven signals propagate through intracellular protein tyrosine kinase of the Syk family. Therefore, Syk and Zap70 protein expressions were analyzed in CLL B cells
and compared with those of normal B cells using flow cytometry. Consistent with previously published results, Syk protein levels were more abundant in most of CLL B cells compared with normal B lymphocytes (Figure 1C and supplemental Figure 2A). Interestingly, significantly higher levels of Syk were detected in the responding B cells compared with nonresponding cells (P = .02; Figure 1C). FISH analysis confirmed that the overexpression of Syk protein was not because of genetic amplification of SYK gene (supplemental Figure 2B). As already reported, Zap70 was detected more in responding cells respective to nonresponding cells and normal B lymphocytes (P = .004; Figure 1D). Together, these results suggested that high IgM, Syk, and Zap70 protein contents might contribute to reach a critical responsiveness threshold on BCR engagement in responding CLL B cells.

Global Syk phosphorylation reflects activation of the responding CLL B cells

We next investigated the constitutive and stimulation-dependent phosphorylation of Syk family members in nonresponding and responding B cell lysates (Figure 1E). Higher levels of constitutive phospho-Syk were detected in responding cells compared with nonresponding cells. Furthermore, although phospho-Syk levels remained low in nonresponding cells on IgM stimulation, increase of phospho-Syk was systematically detected in responding cells. Despite the presence of a substantial amount of Zap70 in some extracts, we did not observe any constitutive or IgM-induced Zap70 phosphorylation. Together, the differences in Syk expression and phosphorylation status in our patient samples are not only reflective of constitutive differences in BCR activation but also of a differential signaling capacity between responding and nonresponding leukemic cells.

Because several tyrosine residues of Syk are targeted for phosphorylation on BCR stimulation, we next examined the phosphorylation status of tyrosine 352 (Y352) by immunoblotting. Although the phosphorylation of Y352 was higher in responding CLL B cells compared with nonresponding cells, enhanced phosphorylation of this particular residue was not observed on IgM triggering for neither of them (supplemental Figure 2C). This result was confirmed by flow cytometry on a larger cohort of patients using the same anti-pY352 Syk antibody (supplemental Figure 2D). Although these results contrast with the global phosphorylation pattern of Syk, they argue for the functional implication of other conserved residues in the signaling capacity of the responding CLL B cells.

Together, these data further suggest a smallest possible requirement for membrane initiators, and early intermediates, to reach threshold levels of stimulatory signals. Cells reaching such levels only might have the capacity to respond on BCR stimulation.

BCR allows phosphorylation of PLCγ2 and calcium mobilization in responding CLL B cells

We next evaluated whether IgM-induced activation also might lead to a differential increase of PLCγ2 phosphorylation. Using Phosflow cytometry analysis (as shown for 2 representative samples in Figure 2A left), anti-IgM stimulation led to considerable increase in pY759 PLCγ2 levels in responding cells compared with unstimulated cells but to minor extent in nonresponding cells. Mean fluorescence intensities were collected from a series of leukemic B cells, and anti-IgM–induced PLCγ2 phosphorylation was calculated for each sample and graphed. Results from a larger series of patients confirmed that PLCγ2 exhibited higher phosphorylation rates in CLL B-cell samples from the responder group compared with the nonresponder group (Figure 2A right), demonstrating that PLCγ2 was differentially activated between the 2 groups of patients.

To delineate the contribution of the BCR-mediated activation on Ca2+ release, we next measured intracellular Ca2+ uptake in both groups of patients. Anti-IgM stimulation did not lead to a significant release of calcium in nonresponding cells but led to efficient uptake of calcium in the responding cells (Figure 2B). Leukemic B cells from both groups showed increased levels of calcium in response to the ionophore ionomycin, demonstrating that the calcium pathway in nonresponding CLL B cells was not altered. Therefore, rapid PLCγ2 phosphorylation and calcium
NFAT2 is constitutively overexpressed and to some extent localizes into the nucleus of CLL B cells

Studies have shown that the BCR/PLCγ2-calcium signaling cascade leads to the subsequent activation of NFAT transcription factors. Although NFAT1 is predominantly expressed in resting T cells, NFAT2 is induced under the positive control of NFAT1 in response to stimulation.29,30 We first evaluated by RT-PCR the transcript levels of NFAT1 and NFAT2 isozymes in CLL cells. Interestingly, both NFAT2 and NFAT1 transcript levels were higher in CLL B cells compared with normal B lymphocytes (Figure 3A and supplemental Figure 3A, respectively). NFAT1 levels in CLL B cells were comparable with those detected in T lymphocytes with supplemental Figure 3A, respectively). NFAT2 proteins in CLL B cells from both groups of patients was with statistical difference was observed (ns).

Together these data suggest that all CLL B cells might be in a preactivated stage, but BCR-mediated signaling is necessary to achieve significant transcriptional activation, as we observed in responding cells. Furthermore, our results indicate that IgM-induced NFAT2 DNA-binding activity discriminates CLL patient groups.

VIVIT peptide inhibitor blocks the BCR-NFAT–dependent pathway in responding CLL B cells

Given that NFAT transcription factors are translocated into the nucleus on calcineurin-dependent dephosphorylation, we tested the specific 11R-VIVIT peptide that effectively competes with NFATs for calcineurin binding.28
of stimulated B cells (Figure 5D). Confirming the competitive effect of VIVIT on NFAT-dependent transcription was a decrease of CD23 membrane expression (Figure 5C). The specific increase of CD23 expression at increasing concentrations of VIVIT showed a dose-dependent transcriptional activity.

In response to BCR ligation, NFAT2 is differentially activated in B cells from both groups of patients (Figure 4A). Nuclear or cytoplasmic extracts from freshly isolated B cells from R (n = 9) and NR (n = 6) cases and from unstimulated or CD3/CD28-stimulated Jurkat cell line (horizontal dashed lines) were analyzed for their NFAT2 DNA-binding ability using an ELISA-derived assay. Competition with a specific oligonucleotide was used to ensure binding specificity (P; probe; n = 3). No statistical difference (ns) was observed between NR and R patient extracts. (B) Nuclear extracts from NR (n = 13) and R (n = 12) cells stimulated or not with an anti-IgM antibody (10 μg/mL/10⁶ cells) for 18 hours were used following the same protocol as described in panel A. Results are presented as fold induction of the NFAT2 DNA-binding activity on stimulation.

Treatment of the cells with VIVIT allowed immunodetection of NFAT2 in the cytoplasm only on stimulation, verifying that nuclear translocation of NFAT2 was fully abolished (Figure 5A).

We next examined the effect of VIVIT treatment on CD23, a direct transcriptional target of NFAT, that is up-regulated on BCR stimulation in responding B cells only.6 RT-PCR analysis showed that BCR triggering induced CD23 transcription in responding cells. Remarkably, cotreatment of the cells with VIVIT strongly inhibited CD23 transcription in response to BCR stimulation (Figure 5B). Indeed, flow cytometry analysis revealed that CD23 protein expression also was increased on BCR stimulation in most responding CLL B-cell samples tested (n = 7). Cotreatment with increasing concentrations of VIVIT showed a dose-dependent decrease of CD23 membrane expression (Figure 5C). The specific competitive effect of VIVIT on NFAT-dependent transcription was confirmed using expression of CD71, a NFAT-independent marker of stimulated B cells (Figure 5D).

The ability of nonresponding cells to propagate signaling downstream of NFAT activation (supplemental Figure 4B) was further confirmed by a dose-dependent induction of CD23 expression on ionomycin treatment (supplemental Figure 4C). Indeed, similar induction was observed in responding cells. Together, these data demonstrated that inhibition of the calcineurin-NFAT complex, through VIVIT treatment, abolished IgM-induced NFAT transcriptional activity.

To determine whether inhibiting calcineurin-NFAT2 pathway might affect BCR-induced survival, the metabolic activity of the cells from both patient groups was evaluated in the presence of the VIVIT inhibitor (Figure 5E). Consistent with our previous results,6 we observed a much stronger increase of the metabolic activity in responding cells (n = 12) compared with nonresponding cells (n = 13; P < .0001). Interestingly, the almost 50% increase of the metabolic activity in responding cells was strongly repressed in the presence of the VIVIT peptide. In contrast, VIVIT treatment of the nonresponding cells led to a minor decrease in their metabolic activity, indicative of a very low toxicity effect on CLL B cells. Furthermore, VIVIT treatment in stimulated responding B cells resulted in metabolic levels comparable with those of the nonresponding B cells, indicating that VIVIT treatment can fully repress NFAT-driven activation pathway in responder cases. In addition, at the opposite of IgM stimulation, ionomycin treatment, that increased NFAT2 transcriptional activity of the nonresponding cells (supplemental Figure 4B), also resulted in a substantial enhancement of the metabolic activity (supplemental Figure 4D). Indeed, an ionomycin-driven activation of the metabolic activity also was observed in responding cells albeit to a lower extend than IgM stimulation. Overall, these results demonstrated that BCR-induced cell survival necessitates the calcium-NFAT signaling pathway and treatment with VIVIT altered the deleterious survival of the most responsive cells.

IgM-induced B-cell survival is relevant for CLL clinical outcome

Finally, we investigated whether the ability to discriminate between responder and nonresponder patients according to their BCR-NFAT pathway activation might be of a clinical relevance. PFS and OS were assessed for the 77 untreated patients enrolled in our study, with a median follow-up of 48.6 and 60.4 months, respectively. PFS was significantly different between the responder and nonresponder group. Although median PFS was not reached for the nonresponder group, the median PFS was 20.3 months for the responder group (Figure 6A; P < .0001, log-rank test). These results demonstrate the pathophysiologic relevance of measuring IgM-induced metabolic activity in CLL B cells. Absence of BCR signaling capacity in vitro was clearly restricted to patients with stable disease, whereas IgM-induced B-cell survival advantage was associated with disease progression. Moreover, individual assessment of the early intermediates argues for the necessity of minimal amounts of these effectors to provoke cellular activation (supplemental Table 2). Even more strikingly, overall survival analysis revealed a clear difference between both groups. Median survival in the responder group was 74.2 months, whereas it was not reached in the nonresponder group. With a median follow up of 60.4 months, only 1 patient died in the nonresponder group, and from a CLL unrelated disease (Figure 6B; P = .0002, log-rank test). Therefore, IgM-induced B-cell survival advantage represents a functional predictor of the aggressive clinical course of CLL.

Discussion

Numerous reports, including ours, indicate an important role for BCR signaling in CLL pathogenesis and disease progression.6,7,10,33 Previously, we have demonstrated that, in vitro, BCR ligation induces a survival advantage in CLL B cells isolated from patients with unfavorable prognostic factors.6 Here, we demonstrate that the differential advantage observed in vitro translates into a striking difference for patient disease evolution. BCR unresponsiveness is clearly restricted to stable CLL cases, whereas BCR signaling...
capacity is associated with disease progression, shorter PFS, and shortened OS. At present, the common prognostic parameters used in the evaluation of CLL do not allow to observe such a discriminative overall survival between the 2 groups. The potential prognostic use of this novel assessment is under investigation on a larger cohort of fully annotated CLL cases by multivariate analysis with the established prognostic markers.

Further dissection of emanating signaling pathways provides evidences for a quantitative role of the initial signalosome components in the differential survival capacity of the cells between patients experiencing unfavorable or favorable clinical outcomes. Our analysis, in line with other reports, describe deregulated expression levels for various components of the BCR signaling complex in CLL B cells compared with normal B cells. In regard to this point, it has been established that low levels of BCR is a hallmark of CLL B cells because of an incorrect folding of both IgM and CD79a,3,8,15,16 However, based on the differential in vitro survival readout, B cells from the responder group express higher surface IgM levels compared with nonresponding cells. These results point out to the importance of IgM-induced signaling all along B-cell development with increasing levels required during both T1-T2 transitional stages and peritoneal differentiation.34 Furthermore, higher levels of IgM altogether with unmutated IGHV might contribute to a better recognition of multivalent antigens, providing stronger survival signals and selection in favor of the pathologic clonal expansion. The difference of surface IgM observed between nonresponding and responding cells suggests that a minimal number of receptor is necessary to reach a responsiveness threshold leading to cell survival. Absence of a significant difference for CD20 coreceptor between the 2 groups of patients is indicative of the central role held by the BCR in the threshold, and this despite the known association of this modulator with the IgM-CD79a-CD79b complex.35

Cytogenetic analysis confirmed that the transcriptional induction of SYK and NFAT2 in CLL B cells was not linked to genetic alteration.30,36 Deregulated expression might therefore be indicative of differential signaling activities in these cells in response to external BCR triggering. Of note, we observed higher levels of NFAT1, predominantly expressed in resting T cells, in the nonresponder group that exhibits low signaling capacity and metabolic activity. Interestingly, CLL B lymphocytes from responder cases expressed, on average, higher amounts of Syk and Zap70 proteins. Our results show also that a minimal amount of Syk or Zap70 is necessary to further propagate the initial signal emanating from the BCR complex and that these protein tyrosine kinases also take part in setting up signaling thresholds. Accordingly, higher expression levels of Syk and/or Zap70 might compensate lower levels of surface IgM in responding cells. Conversely, lower levels of Syk and Zap70 hinder higher membrane levels of IgM in nonresponding cells, adding value to compensatory expression levels (supplemental Table 2).

Consistent with our previous findings, constitutive tyrosine phosphorylation of Syk is observed in CLL B cells. Furthermore, it allows for a distinction between the 2 groups of patients.6,7,18,30,37 In

**Figure 5.** VIVIT peptide inhibitor blocks the BCR/NFAT-dependent pathway in responding CLL B cells. 
(A) NFAT2 immunofluorescence staining of CLL B cells from 1 representative R case (n = 3) stimulated or not in the presence or not of NFAT inhibitor 11-R VIVIT (5 µM for 24 hours). Scale bar corresponds to 5 µm. 
(B) Quantitative RT-PCR analysis of CD23 transcript expression levels in freshly isolated B cells from R cases (n = 5) on stimulation with anti-IgM (10 µg/mL) in the presence or not of 11-R VIVIT (5 µM). CD23 mRNA expression was normalized on ABL transcript expression in each tested sample, and results were graphed. Cell surface expression of CD23 protein (C) or CD71 protein (D) was determined using flow cytometry analysis on CLL cells from 7 (C) or 8 (D) R cases stimulated with anti-IgM (10 µg/mL) in presence of increasing concentrations (0, 2, and 5 µM) of 11-R VIVIT. Levels are indicated as fold increase on stimulation. 
(E) Fold increase of metabolic activity (% MTS) was determined on 48-hour BCR stimulation for 13 NR and 12 R cases. B lymphocytes were incubated in the presence or not of 11-R VIVIT (5 µM).
accompanying with its weak affinity for the BCR, the presence of Zap70 does not influence the basal phosphorylation of Syk. The differential constitutive phosphorylation of Syk may be because of the chronic exposure of the BCR to various soluble autoantigens and to the quantitative enhancement of both IgM and Syk expression in responding cells. Our discrimination between the 2 groups of patients is further supported by an increased Syk phosphorylation on IgM stimulation in B cells from responder cases only. In both constitutive and stimulatory contexts, the absence of further phosphorylation in the presence of Zap70 rather argues for an adaptor function of Zap70 in the recruitment of downstream signaling effectors. Therefore, we show that, in addition to BCR levels and structure, levels and activation of several downstream intermediates are also essential for the differential activation of the cells.

Given the stepwise activation of Syk and the alternative presence of Zap70, we also delineated the global activation status of the cells through the analysis of PLCγ2 activation and calcium flux. Differential activation was observed for both of these targets between responding and nonresponding CLL B cells. Furthermore, analysis of pY759 PLCγ2 seems to be a more reliable activation marker than other intermediates and kinases, including Syk/Zap70, Src family kinases (such as Lyn), or Btk, whose levels are all highly variable in CLL cells. Therefore, IgM-dependent PLCγ2 Y759 phosphorylation may serve as a potential biomarker of evolutivity in CLL and may be used as readout of the efficacy of Syk or Btk inhibitors. It is also tempting to speculate that specific PLCγ2 inhibitors might be developed.

Together, our study shows that the survival advantage of responding cells is the result of a balanced expression of early intermediates that establish a threshold for a cellular response. Once this threshold is reached, cells become responsive and maximize their signaling capacity by up-regulating intracellular effectors imposing a pressure for expansion through self-activation.

In terms of downstream signaling pathways, sustained engagement of the BCR results in significantly prolonged activation of Akt and ERK kinases and enhanced degradation of the NF-κB inhibitor IκB. BCR engagement induces activation of transcription factors, such as NFATs, that are major effectors of long-term biologic responses in B lymphocytes, including proliferation, survival, and differentiation. Our studies demonstrated that NFAT2 overexpression in unstimulated CLL B cells is associated with increased nuclear localization and transcriptional activity, responses that are not observed in unstimulated normal peripheral B lymphocytes. The weak constitutive NFAT2 DNA-binding activity observed in all CLL B cells might be indicative of the continuous exposure of the leukemic cells to antigens, leading to some anergic phenotype. These properties, together with a restricted BCR repertoire, CD5 expression, active signal transducer and activator of transcription 3, and natural IgM antibodies production are shared between CLL and murine B1a cells. In mice, NFAT2 genetic invalidation dramatically affects the B1a cellular compartment, whereas NFAT2 overexpression in NFAT2−/− B cells partially rescues the development and survival of these cells. We demonstrated that NFAT2 DNA-binding activity is induced on IgM ligation in CLL B cells from the responder group only. Thus, the active IgM-dependent signaling might allow for bypassing the anergic process in this group, but nonresponding cells could not overcome threshold levels. Accordingly, ionomycin treatment that shunts upstream molecular intermediates of the BCR signaling pathway restores induction of NFAT2 DNA-binding in nonresponding cells. However, the global lower responsiveness of these cells also argues for the requirement of upstream BCR signaling to bypass the anergic process.

To demonstrate the functional implication of NFAT2 as a biomarker in CLL B cells, we used the NFAT-specific inhibitor 11R-VIVIT, shown to be more selective than cyclosporin A and FK506, and a biomarker that can actively compete for calcineurin binding to block NFAT dephosphorylation. VIVIT robustly blocked nuclear translocation of NFAT on stimulation in responding CLL B cells. Remarkably, trapping NFAT2 into the cytoplasm by VIVIT treatment resulted in a clear effect on cell survival in responding CLL B cells. Inhibition of NFAT nuclear translocation led responding CLL B cells to resemble nonresponding cells. Conversely, translocation of NFAT via ionomycin treatment induced nonresponding cells to resemble responding cells. These results demonstrate the essential role of NFAT in maintaining the cell-fate balance of these cells. Consistent with the role of NFATs as transcriptional regulators, VIVIT treatment blocked the expression of CD23, a direct transcriptional target of NFAT2. Interestingly, membrane CD23 has been targeted for antibody therapy in CLL disease. This type of treatment leads to B-cell apoptosis, further supporting a role for CD23 in CLL B-cell survival. The self-activating loop of the responding CLL B cells might therefore be a powerful target for therapy in patients who present a
progressive profile. This potential therapeutic avenue should be further investigated.

We demonstrate that nonresponding and responding CLL B cells exhibit differential signaling downstream of the BCR, in terms of IgM-induced global Syk phosphorylation, PLCγ2 activation, calcium release, and NFAT2 transcriptional activity. In addition, our study supports the usefulness of these various intermediates as more practical functional markers of B cells from CLL patients who have an unfavorable clinical course. In terms of therapeutic options, several intermediates of the signaling cascade might be promising targets for disease treatment. For example, the NFAT inhibitor peptide VIVIT, which does not compromise non-NFAT–mediated calcineurin signaling, abolishes cell survival response specifically generated downstream of BCR ligation.

Acknowledgments

The authors are grateful to Dr. R. Balderas (BD Biosciences, US), J. F. Mathieu and F. Navarro (BD Biscoiences, Europe) for providing flow cytometry reagents and antibodies directed against Syk and PLCγ2 proteins and their phosphorylated forms. BAC clones RP11-91C19 and RP11-803N2 were kindly provided by Dr. S. Romana (Equipe Mixte Inserm 0210, Hôpital Necker Enfants Malades, Paris, France). They acknowledge S. Georges for assistance in sample preparation and Dr. L. Izzi (Montréal, QC) for critical reading of the manuscript.

This study was supported by Inserm, University Paris Nord, and grants from Ligue Nationale Contre le Cancer, Association pour la Recherche contre le Cancer, Fondation de France, and Fondation pour la Recherche Médicale. C.L.R. was the recipient of a Servier ParisBio fellowship. P.A.D. and N.C. were recipients of Fondation pour la Recherche Médicale and Société Française d’Hématologie fellowships.

Authorship

Contribution: C.L.R., P.-A.D., N.C., T.B., and M.Q. performed the experiments and analyzed the data; V.E. performed FISH experiments; R.L. shared expertise in flow cytometry experiments; C.L.R. and P.A.D. designed the figures and wrote the manuscript with F.A.-C. and N.V.-B; V.L. and F.A.-C. provided patient samples with biologic criteria; and M.B. and V.L. performed statistical analysis.

Conflict-of-interest disclosure: The authors declare no competing financial interests.
