A nitric oxide synthase (NOS)–like activity has been demonstrated in human red blood cells (RBCs), but doubts about its functional significance, isoform identity and disease relevance remain. Using flow cytometry in combination with the nitric oxide (NO)–imaging probe DAF-FM we find that all blood cells form NO intracellularly, with a rank order of monocytes > neutrophils > lymphocytes > RBCs > platelets. The observation of a NO-related fluorescence within RBCs was unexpected given the abundance of the NO-scavenger oxyhemoglobin. Constitutive normoxic NO formation was abolished by NOS inhibition and intracellular NO scavenging, confirmed by laser-scanning microscopy and unequivocally validated by detection of the DAF-FM reaction product with NO using HPLC and LC-MS/MS. Using immunoprecipitation, ESI-MS/MS-based peptide sequencing and enzymatic assay we further demonstrate that human RBCs contain an endothelial NOS (eNOS) that converts L-3H-arginine to L-3H-citrulline in a Ca2+/calmodulin-dependent fashion. Moreover, in patients with coronary artery disease, red cell eNOS expression and activity are both lower than in age-matched healthy individuals and correlate with the degree of endothelial dysfunction. Thus, human RBCs constitutively produce NO under normoxic conditions via an active eNOS isoform, the activity of which is compromised in patients with coronary artery disease. (Blood. 2012;120(20):4229-4237)

Introduction

The key event in the pathogenesis of arteriosclerosis is believed to be a dysfunction of the endothelium with disruption of vascular homeostasis, predisposing blood vessels to vasoconstriction, inflammation, leukocyte adhesion, thrombosis, and proliferation of vascular smooth muscle cells. Red blood cells (RBCs) are typically considered as shuttles of respiratory gases and nutrients for tissues, less so compartments important to vascular integrity. Patients with coronary artery disease (CAD) and concomitant anemia have a poorer prognosis after myocardial infarction, percutaneous coronary intervention, and coronary artery bypass grafting, and are more prone to developing heart failure with fatal outcomes.1-3 Surprisingly, erythropoietin treatment fails to improve diagnosis, more prone to developing heart failure with fatal outcomes.1-3

Nitric oxide (NO) is an essential short-lived signaling/regulatory product of a healthy endothelium that is critically important for vascular health. Decreased production and/or bioactivity of NO are a hallmark of endothelial dysfunction and have been shown to contribute to accelerated atherogenesis. In the cardiovascular system, NO is continuously produced in endothelial cells (ECs) by the type III isoform of NO synthase (eNOS, NOS3; EC 1.14.13.39).4 In addition to endothelial cells, some circulating blood cells also contain eNOS.

It is an accepted dogma that RBCs take up and inactivate endothelium-derived NO via rapid reaction with oxyhemoglobin to form methemoglobin and nitrate, thereby limiting NO available for vasodilation. Yet it has also been shown that RBCs not only act as “NO sinks” but synthesize, store, and transport NO metabolic products. Under hypoxic conditions in particular, it has been demonstrated that RBCs induce NO-dependent vasorelaxation.5,6 Mechanisms of release and potential sources of NO in RBCs are still a matter of debate, but candidates include iron-nitrosyl-hemoglobin,7 S-nitrosohemoglobin,8-10 and nitrite. The latter may form NO either via deoxyhemoglobin5,11 or xanthine oxidoreductase (XOR)–mediated reduction,6,12 or via spontaneous12 and carbonic anhydrase-facilitated disproportionation.13 Most of these processes show a clear oxygen-dependence, and several are favored by low oxygen tensions. The relative contribution of either mechanism to NO formation varies with oxygen partial pressure along the vascular tree. In addition, RBCs release ATP when subjected to hypoxia, providing an alternative vasodilatory pathway.14
In contrast to hypoxia-induced NO release from RBCs, their generation of NO under normoxic conditions is less well characterized. Data from our and other laboratories have demonstrated a NOS-dependent NO production from RBCs in normoxia, suggesting that RBCs may contribute to the inhibition of platelet aggregation, the circulating pool of NO metabolites, and to overall tissue protection. Treating RBCs with NOS inhibitors decreased accumulation of NO metabolites and citrulline in the supernatant. However, Kang et al failed to measure citrulline production in RBC lysates, maybe because of loss of cellular structures or cofactors important for activity. Another recent study failed to detect increases in labeled nitrite/nitrate after the addition of L-Arg to intact RBCs. RBCs have been shown to express a protein containing epitopes of an eNOS. However, positive staining with anti-iNOS antibodies has also been reported, and others suggested that RBCs might express a novel NOS isoform. Thus, doubts about the functional significance of the NOS-like activity in RBCs remain, and little is known about NOS isoform identity and disease relevance.

We therefore sought to definitively identify and characterize the activity of human red cell NOS using an advanced multilevel analytical approach. Using HPLC, LC-MS/MS, flow cytometry, laser scanning microscopy, and enzymatic assay together with functional studies we here demonstrate that human RBCs contain an active eNOS that gives rise to constitutive intracellular NO formation under normoxic conditions. We further show that this activity is compromised in CAD and correlates with the degree of endothelial dysfunction.

Methods

Study subjects

Blood drawn from human healthy subjects (25-33 years) was used for biochemical characterization of human red cell eNOS. To compare NOS expression with vascular function, 10 patients with endothelial dysfunction because of coronary artery disease (CAD), as diagnosed by coronary angiography, and 9 age-matched healthy subjects were recruited from the outpatient clinic of the Department of Cardiology, Pulmonology, and Angiology, Düsseldorf University Hospital. NOS activity was quantified in red cells from a randomized subset of the study population composed of 4 healthy individuals and 5 patients with CAD. All subjects provided written informed consent before enrollment. Procedures were conducted in accordance with the Declaration of Helsinki and approved by the local ethics committee of the Heinrich-Heine University of Düsseldorf.

Endothelium-dependent dilation of the brachial artery was assessed noninvasively by measurement of flow-mediated dilatation (FMD) using high-resolution ultrasound (VIVID i, GE Healthcare). FMD and endothelium-independent dilation were expressed as a percentage change from baseline. See supplemental Methods for further details (available on the Blood Web site; see the Supplemental Materials link at the top of the online article).

Comparative flow cytometric analysis of blood cells

Three aliquots of blood were processed for analysis of leukocytes, RBCs, and platelets, as described in supplemental Methods. Briefly, each aliquot was loaded with 10 μM DAF-FM diacetate for 30 minutes at room temperature in the dark, or left untreated, washed in PBS and analyzed for intracellular NO. Intracellular NO was scavenged by incubation of RBC suspensions for 30 minutes at 37°C with 250 μM iron diethylthiocarbamate (Fe[DETC]2) prepared as described, and then washed by centrifugation at 300g for 10 minutes at 4°C. Aliquots from these preparations were analyzed within 15 minutes in a FACS Canto II flow cytometer after further 1:3 dilution in PBS. Flow cytometric data were collected using the DIVA 5.0 software package and analyzed using FlowJo V7.5.5 (TreeStar). Median fluorescence intensity (MFI) was calculated from the histogram (distribution) plots of the green fluorescence signals (Ex 488 nm, Em 530 ± 30 nm) detected within the cell-specific gates (see Figure 1A1, Bi, and C, gated cells are color-coded). MFI of untreated samples served as autofluorescence controls. The acquisition voltage was adjusted before each measurement according to the position of the third fluorescence peak of standard latex beads (Rainbow beads, BD Bioscience).

Visualization of DAF-FM fluorescence in RBC by laser-scanning microscopy

Whole blood was diluted 1:10 in PBS and treated with 10 to 30 μM DAF-FM diacetate for 30 minutes at room temperature or 37°C in the dark, washed and treated with 100 μM spermine/NO (Sper/NO), or 100 μM S-nitrosocysteine (SNOC) for 15 minutes. Unstained cells served as autofluorescence controls. Blood smears were analyzed 1 to 5 minutes after preparation under a Zeiss LSM 510 confocal laser-scanning microscope using a Zeiss Plan Neofluar 63×/1.3 oil DIC objective and excitation (Ex) 488 nm with UV/488/543/633 nm beam splitter. Fluorescence was recorded using a 540 to 30-nm bandpass filter and micrographs were taken at 37°C. Images were processed with Adobe Photoshop CS5 (Adobe Systems GmbH).

HPLC analysis of the nitrosation products of DAF-FM

Red cell pellets were diluted 1:500 in PBS, pretreated as described in the “Flow cytometry” section, washed, and loaded by 30 minutes incubation with 10 μM DAF-FM diacetate at room temperature in the dark. After centrifugation at 300g for 10 minutes at 4°C, pellets were incubated with HPLC-grade DMSO for 30 minutes at room temperature in the dark and spun down at 13 000g for 10 minutes. The supernatants were analyzed by reversed-phase high performance liquid chromatography (HPLC) applying a method described for DAF-2 with some modifications, using an Agilent 1100 Series HPLC system (Agilent Technologies) with a diode array detector (set to 490 nm) and a fluorescence detector (Ex 490, Em 517) connected in series. The column used was a Phenomenex Luna C18 (2), (4.6 × 250 mm; 5 μm) fitted with a guard column, both kept at 25°C. The mobile phase consisted of 0.05% TFA in water (A) and 0.05% TFA in acetonitrile (B), using the following gradient settings (time/%A): 0 minutes–95%, 40 minutes–60%, 45 minutes–60% with a flow rate of 1 mL/min.

Identification of DAF-FM reaction products by LC-MS/MS

Mass spectra were run on an Agilent 6400 triple-quadrapole liquid chromatography mass spectrometry (LC-MS/MS) instrument operated in positive ion mode; samples were separated using a Kinetix C18 (2) column (2 × 50 mm; Phenomenex) with 0.1% aqueous formic acid (A) and methanol (B) as mobile phase (flow rate 200 μL/min, gradient [time, %A]): 0 minutes–80%, 1 minute–80%, 2.1 minute–30%, 3.1 minute–30%, 3.5 minutes 80%, 5 minutes–80%). DAF-FM (transition 413.2 → 369.12) and DAF-FM-T (transition 424.2 → 380.1) were detected using selective-reaction monitoring.

Immunoprecipitation, gel electrophoresis, and Western blot analysis

Crude protein extract was obtained by lysis of RBC pellets (1 mL) with tolulene. ECLs were lysed as described. Total protein concentration was determined by Lowry (DC Protein Assay, Bio-Rad). Probes (100 μg/L protein) were incubated for 1 hour at room temperature with a mouse anti-human NOS3 antibody (40μg; BD Bioscience). Immunocomplexes were isolated by magnetic separation using protein G Dynabeads (Invitrogen) following the manufacturer’s instruction. For gel electrophoresis, samples were loaded onto 7% NuPAGE Novex Tris/Acetate precast gels (Invitrogen), and protein bands were stained with colloidal Coomassie Brilliant Blue. Western blot analysis was performed as previously
described\textsuperscript{30} using rabbit anti-NOS3 antiserum (1:1000; BD Bioscience) and HRP-conjugated goat anti-rabbit antibody (1:5000; Rockland).

**Peptide sequencing by ESI-MS/MS**
In-gel digestion and peptide separation was performed as described in supplemental Methods. Eluting ions were transferred directly into a LTQ XL linear ion trap mass spectrometer (Thermo Fisher Scientific) equipped with an electrospray ionization device (spray voltage 1.8 kV, capillary temperature 180°C). Precursor ions were detected in a full MS scan from 400 to 2000 m/z. Full MS/MS spectra were acquired for the 10 most intense signals using a fill time of 100 ms for each MS/MS \( m \) ppm. MS/MS spectra were interpreted with the SEQUEST algorithm implemented in the Proteome Discoverer software (Thermo Fisher Scientific) and searched against the human Swiss-Prot database (release 15.6/57.6). Peptide mass accuracy for precursor ions and tolerance for fragment ions were, respectively set to 2.5 and to 1 atomic mass units, allowing methionine oxidation as a possible chemical modification.

**Peptide alignments**
Peptide sequences were aligned with the sequences of all main NOS isoforms and eNOS splice variants using the constraint-based multiple alignment tool (COBALT) of the NCBI website (protein accession numbers NP\_000611 = NOS1, nNOS; NP\_000616 = NOS2, iNOS; NP\_000594 = NOS3, isoform 1; with splicing variants of NOS3 as NP\_001153581 = NOS3, isoform 2, NP\_001153582 = NOS3, isoform 3, and NP\_001153583 = NOS3, isoform 4). The position of the peptides in the conserved regions was visualized using Geneious Version 5.4 software (Biomatters).

**Determination of NOS activity**
The activity of the immunoprecipitated protein was determined by measuring the rate of conversion (fmol/min) of \([^{1}H]\text{L-arginine}\) to \([^{1}H]\text{citrulline}\) or \([^{14}C]\text{L-arginine}\) to \([^{14}C]\text{citrulline}\) as previously described. In the absence or presence of the specific NOS inhibitors L-NAME (1mM each), or of Ca\(^{2+}\) (75\(\mu\)M) + calmodulin (0.04 \(\mu\)g/\(\mu\)L; see supplemental Methods for details).

**Results**

**RBCs loaded with DAF-FM are fluorescent**
To compare intracellular NO production between circulating blood cells, blood fractions enriched in leukocytes, platelets and erythrocytes were loaded with DAF-FM diacetate and analyzed by flow cytometry (Figure 1). Individual cell subpopulations were identified by staining with specific surface markers and by analysis of scatter dot plots (Figure 1A-C, subpanel i). Monocytes revealed the highest intracellular fluorescence intensity, followed by neutrophils, lymphocytes, RBCs, and platelets (Figure 1D). Whether these variations are because of differences in NO and/or reactive oxygen species (ROS) production, or dye uptake-processing remains to be investigated.

A DAF-FM–related fluorescence signal in RBCs was unexpected given the abundance of the NO scavenger oxymemoglobin and the nitrosation scavengers glutathione and ascorbate in these cells. However, these original findings were confirmed by laser scanning microscopy (Figure 2A). DAF-FM-associated fluorescence was remarkably uniform with a typical doughnut-shaped fluorescence pattern, and strongly increased after addition of the NO donors Sper/NO (Figure 2A bottom panel) or S-nitrosocysteine. Fluorescence intensity varied up to 5-fold between cells of the same preparation (see histogram plot in Figure 1Bi and Figure 2B), was sensitive to changes in incubation temperature (37°C \(\geq\) RT), and oxygen tension (21% O\(_2\) \% \(\geq\) 5% O\(_2\)). Median fluorescence intensity (MFI) increases were markedly (20%-70%) inhibited by either preincubation of cells with the NOS-inhibitors, L-NAME (Figure 2C) and L-NIO (n = 6, \( P = .048 \)) or untreated control), or the lipophilic NO scavenger Fe\([\text{DETC}]_{2}\) (Figure 2D). This degree of inhibition is probably maximal considering the strong background fluorescence because of the formation of unspecific fluorescent adducts and the presence of fluorescence impurities in the DAF-FM DA stock solution (see next section). Moreover, treating RBC with nitrite did not affect DAF-FM-dependent signal under neutral conditions, whereas at pH 5.5 only higher concentrations of nitrite (> 200\(\mu\)M) strongly increased intracellular fluorescence (data not shown).

Unexpectedly, MFI did not increase on addition of L-arginine (3mM) to intact cells. These findings are consistent with the lack of \(^{15}\text{N-nitrite/nitrate} production after incubation of RBCs with exogenous \(^{15}\text{N-L-Arg}^{14}\) and indicate that constitutive red cell NOS activity does not rely on extracellular substrate supply. By contrast, treatment with the nitrosating NO donor SNOC markedly increased fluorescence intensity in a concentration-dependent manner (Figure 2B) and this was inhibited by addition of Fe\([\text{DETC}]_{2}\) (as assessed by fluorimetry (not shown). Intermediate SNOC concentrations produced fluorescence intensity distributions distinct from those at other concentrations, suggesting cell-to-cell differences in SNOC uptake and/or metabolism (Figure 2B). Peak MFI at maximal NO donor concentrations were similar and cell-to-cell variations small, indicative of comparable DAF-FM loading efficiencies. Thus fluorescence intensity variations at baseline likely reflect differences in constitutive NO activity between cells. None of these treatments affected RBC morphology, as assessed in the transmitted light channel of the laser scanning microscope and by the lack of positional changes for the RBC population in the scatter dot plot using flow cytometry. Qualitatively identical results were obtained using fluorimetry (not shown). Although no changes in cell morphology or hemolysis were observed with these treatments at the concentrations used (which could have impeded flow cytometric analysis), a high NO/NOS-independent background signal was apparent using these techniques, even after correction for autofluorescence.

**DAF-FM–related fluorescence in RBCs originates from reaction with NOS-derived NO**
To confirm that the fluorescent signals detected by fluorimetry, laser scanning microscopy and flow cytometry were indeed because of intracellular nitrosation of DAF-FM to form DAF-FM-T, we analyzed the products of this reaction by HPLC and LC-MS/MS. A peak corresponding to DAF-FM-T (Figure 3C) was detected in RBCs pre-treated with either the NOS inhibitor, L-NAME (Figure 3A middle panel and C, 10 of 12 samples; n = 6, \( P = .048 \)) and the lipophilic NO scavenger Fe\([\text{DETC}]_{2}\) (Figure 3A bottom panel and D). Fluorescence quenching effects of the dark-colored Fe\([\text{DETC}]_{2}\) can be excluded because excess compound was removed by the washing steps before DAF-FM-T extraction.
When plotting the area of the fluorescent peaks obtained by serial dilution of DAF-FM-T standards in RBC lysates against triazole concentrations (assuming 100% conversion efficiency of DAF-FM authentic standard into DAF-FM-T by reaction with SNOC) a linear relationship was apparent (Figure 3E; $R^2 = 0.9989; P < .0001$). By interpolating the areas of the DAF-FM-T related peaks observed in $1.2 \times 10^7$ DAF-FM–loaded RBCs under basal conditions, we estimated that the average concentration of DAF-FM-T in these samples was $64 \pm 12\text{nM (n = 19)}$. Assuming the reaction stoichiometry to be 1:1, the amounts of NO and/or nitrosating equivalents produced by a single RBC within 30 minutes at RT corresponds to at least $3.2 \times 10^{-6}$ fmoles (Figure 3F).

**RBCs contain the “classic” eNOS isofom**

Having identified an intracellular constitutive NOS activity in RBCs, we next sought to isolate and identify the NOS isofom expressed in these cells. Crude hemolysates were prepared by osmotic lysis of RBC pellets with toluene/H$_2$O 1:1, which preserves protein structure and activity and avoids excessive dilution. We succeeded in immunoprecipitating an eNOS-like protein using a mouse monoclonal anti-eNOS antibody, either after enrichment of calmodulin-binding proteins by affinity chromatography (Figure 4A lanes 1 and 2) or directly from crude red cell lysates (Figure 4A lanes 3-4 and B). After separation of the proteins by SDS-PAGE
Isolated red cell eNOS protein is catalytically active

To verify that the erythrocite eNOS identified is indeed active we measured the ability of the immunoprecipitated protein to catalyze the in vitro conversion of $^3$H-L-arginine to $^3$H-citrulline in the presence of NADPH, FAD, FMN, Ca$^{2+}$ and calmodulin. Figure 4E depicts the results from 5 independent experiments (ANOVA $P < .05$). We found that the protein is capable of producing 9.82 fmol/min citrulline under optimal substrate/cofactor supply conditions. Moreover, arginine to citrulline conversion was significantly inhibited by addition of the NOS inhibitor L-NAME (Figure 4E, IP versus IP + L-NAME $P < .05$) and markedly decreased in the absence of Ca$^{2+}$/calmodulin (Figure 4E, IP vs IP without Ca$^{2+}$/CaM; $t$ test $P < .05$). Thus, the isolated eNOS is active and dependent on Ca$^{2+}$/calmodulin interaction.

Red cell eNOS expression and activity are compromised in patients with coronary artery disease

We explored endothelial function and erythrocytic eNOS expression levels and activity in patients with CAD, a condition associated with endothelial dysfunction, and age-matched healthy individuals. Clinical characteristics of the study population are summarized in supplemental Table 1. As expected, flow-mediated dilation of the brachial artery was significantly decreased in CAD patients, whereas maximal vasodilatation in response to GTN was not significantly different (supplemental Table 1). Patients with endothelial dysfunction showed a significantly lower expression of red cell eNOS compared with aged-matched healthy individuals (Figure 5A; mean red cell eNOS expression was 0.519 ± 0.083 vs 1.058 ± 0.55, $t$ test $P < .0001$). Furthermore, univariate regression analysis revealed that erythrocytic eNOS expression correlated with endothelial function in humans ($R^2 = 0.318$, $F = 12.144$, $P = .002$; Figure 5A). Red cell eNOS activity was measured in a randomized subgroup of the study population by analyzing the conversion of $^{14}$C-Arginine into $^{14}$C-Citrulline catalyzed by the isolated protein (Figure 5B). We found that red cell eNOS activity was also significantly decreased in patients with endothelial dysfunction compared with the healthy control group ($P = .0037$, unpaired $t$ test; Figure 5B). Taken together, these results indicate that human red cell eNOS activity mirrors vascular endothelial function.

Discussion

The key findings of our study are: (1) formation of NO and related nitrosative species occurs constitutively in all subtypes of human blood cells, with cell-specific intensity differences; (2) intracellular NO formation can be visualized in RBCs using diaminofluoresceins despite the abundance of the NO scavenger oxyhemoglobin and the nitrosation scavengers glutathione and ascorbate; (3) human RBCs contain a catalytically active version of the classic endothelial NOS isoform (eNOS, NOS3) that converts L-arginine to L-citrulline in a Ca$^{2+}$/calmodulin-dependent manner; (4) both expression and activity of red cell eNOS are compromised in CAD patients; and (5) the extent of eNOS impairment in RBCs correlates with the degree of endothelial dysfunction, demonstrating disease relevance of this blood cell derived NO activity.

Visualization of NO formation in blood cells and fluorescent probe chemistry

By comparing intracellular fluorescence intensities of different cell subpopulations from the same blood sample loaded with DAF-FM diacetate, almost the same fluorescence intensity was apparent in

under reducing conditions followed by coomassie staining, a band of $\sim$135 kD was apparent in all samples (Figure 4A). The identity of this 135 kD band was confirmed by Western blotting using a polyclonal rabbit anti-human eNOS antibody (Figure 4B). Similar results were obtained using the rabbit antibody for immunoprecipitation and the mouse antibody for detection, as well as by staining the membrane with a mouse monoclonal anti-eNOS antibody directed against a different epitope of eNOS. No high-molecular-weight bands were detected if a mouse antibody was used for immunoprecipitation, or by adding antibodies and beads to a serum albumin solution. To identify the immunoprecipitated protein(s), the 135 kD bands of 2 independent coomassie-stained gels were excised (one of them shown in Figure 4C) and subjected to analysis by liquid chromatography-mass spectrometry (LC-MS/MS). 4 different peptides all belonging to eNOS were identified. By alignment of the sequences of these peptides with those of the 3 NOS isoforms including all known splice variants of eNOS, we found that the identified peptides belong to 2 distinct, highly conserved regions of the reductase domain of the NOS protein (Figure 4D): the FMN reductase-like region (peptides 1 and 2) and the ferredoxin reductase (FNR)-like region (peptides 3 and 4) within the FAD-binding pocket (Figure 4D). All 4 peptide sequences showed 100% pairwise identity only with the full eNOS sequence, with peptides 3 and 4 aligning within a region in the C-terminal domain that is absent in the truncated splice variants. Thus, these results show that human RBCs carry a NOS3, the “classic” eNOS isoform constitutively expressed in endothelial cells.

Figure 2. Visualization of intracellular NO production in RBCs. (A) Laser scanning micrographs of RBCs loaded with DAF-FM before (top) or after pretreatment with 3 mM L-NAME (inset) and further incubation with 100 μM Sper/NO (bottom). Please refer to “Methods” for details. (B) Fluorescence distribution plot of untreated cells (front lane), cells loaded with DAF-FM only (second lane), or further treated with 1 to 500 μM SNOC (other lanes). Representative data from 6 experiments (C) Decrease in intracellular RBC fluorescence (ΔMFI) as assessed by flow cytometry after treatment with the NOS inhibitor L-NAME. (D) Intracellular RBC fluorescence (ΔMFI) after treatment with the NO scavenger Fe[DETC]$_2$. ΔMFI = median fluorescence intensity – background fluorescence.

Figure 5B). Taken together, these results indicate that human red cell eNOS activity mirrors vascular endothelial function.
RBCs as in lymphocytes, and only ∼2- to 3-fold lower values than in neutrophils (granulocytes) or monocytes. In blood of healthy individuals, the number of RBCs is approximately 3 orders of magnitude higher than the number of white cells. Our findings thus indicate that in the human circulation, RBCs not only transport the bulk of nitrite, the major intravascular NO storage form that becomes bioactivated under hypoxic conditions, but also represent the largest cellular compartment in which NO is produced under normoxic conditions.

Although diaminofluoresceins are the most frequently used and best investigated NO imaging probes, they do not react with NO directly. Initially, it was proposed that DAF-derivatives might interact with reactive nitrosating species derived from the reaction of NO with O₂ such as N₂O₃ or nitrous acid, to form intermediary N-nitrosamines that are subsequently converted to the highly fluorescent triazole derivatives, DAF-2T or DAF-FM-T. However, N₂O₃ is not likely to be formed efficiently in aqueous biologic environments, except in lipid membranes. Therefore, Wardman argued that DAFs may undergo one-electron oxidation to an anilinyl radical that subsequently reacts with NO in a radical-radical reaction. Both mechanisms are probably operating in concert inside cells. Although the former may explain the abundance of DAF-FM related fluorescence in membrane-rich compartments, the latter complicates the interpretation of results solely based on DAF-FM related fluorescence because of dependence of the latter on ROS formation. Because RBCs are particularly rich in the NO-scavenger hemoglobin.
Origin of constitutive NO synthesis within RBCs

Using an advanced multilevel analytical approach we have provided unequivocal evidence for the conversion of DAF-FM into DAF-FM-T by NO formed by RBCs under normoxic conditions. RBCs contain both a constitutive Ca\(^{2+}\)-dependent NOS containing epitopes of an eNOS\(^{6,15,16,25}\) and an active XOR. Thus, enzymatic NO synthesis in RBCs might occur either via NOS-catalyzed L-arginine to citrulline conversion\(^{15,16,18}\) or by XOR-mediated nitrite reduction.\(^{6,12,40}\) We found that NO-DAF-FM-T was formed in the presence of the specific NOS inhibitors L-NAMe and L-NIO, or by treating RBCs with Fe[DETC]\(_2\), which is commonly used as NO spin-trap in ESR studies.\(^{27}\) Similar results were obtained using flow cytometry. RBC preincubation with nitrite under normoxic conditions did not affect intracellular fluorescence either, ruling out a major role for nitrite in normoxic NO production detectable by DAF-FM. At pH 5.5 higher concentrations of nitrite (> 200μM) strongly increased intracellular fluorescence. Collectively, these results demonstrate that under normoxic conditions constitutive NO production in RBCs is largely NOS-dependent, whereas under hypoxic conditions it may involve nitrite reduction by deoxyhemoglobin,\(^{5,11}\) XOR, carbonic anhydrase,\(^{11,12}\) and/or eNOS itself.\(^{6,12}\)

Activity of a red cell NOS may be involved in the regulation of RBC lifespan,\(^{41}\) deformability,\(^{16,42,43}\) and potentially red cell velocity and blood flow.\(^{43}\) This notion is in line with previous findings showing that NOS inhibitors abolish the antiplatelet effects of RBCs in vitro\(^{15,16}\) and decrease the level of NO products released by isolated RBCs,\(^{16,23}\) however they do not affect intracellular nitrite concentrations.\(^{44}\) Thus RBCs may also contribute to vascular homeostasis, independent of their “classic role” as transporters of oxygen, energy substrates and nutrients. Given the contribution RBCs make to the circulating NO pool and their role in hypoxic vasodilation\(^{45}\) further studies are warranted to address its functional significance for the regulation of RBC function and beyond.

Isolation, isoform identification, and activity of red cell eNOS

Previous studies used antibodies directed against eNOS and iNOS epitopes for Western blotting or immunocytochemistry to probe for the presence of a NOS in RBCs and activity assays to measure either the RBC-dependent conversion of radiolabeled arginine into citrulline or the formation of NO oxidation products. Delicostanti- nos et al isolated the protein by affinity chromatography using LC-MS/MS sequencing; depicted is the fragmentation spectrum of the peptide AQSQAQQGLR. (D) Alignment of peptides identified by LC-MS/MS with sequences of nNOS, iNOS and all known eNOS splice variants. Top panel: Peptides 1 and 2 aligned within the FMN reductase-like region (FMN binding region), whereas peptides 3 and 4 aligned with the ferredoxin reductase (FRN-like) region (FAD and NADPH binding region). CysJ indicates sulfite reductase, α subunit (flavoprotein) region. NOS oxygenase indicates nitric oxide synthase eukaryotic oxygenase domain. Bottom panels: The sequences shown in detail and compared with the other NOS isoforms. The sequences of the peptides are identical with NOS3, isoform 1 only. NP_000611 = NOS1, nNOS; NP_000594 = NOS2, iNOS; NP_000594 = NOS3, isoform 1. Splice variants of NOS3 are NP_001153581 = NOS3, isoform 1, NP_001153582 = NOS3, isoform 3, NP_001153583 = NOS3, isoform 4. (E) Activity of an advanced multilevel analytical approach we have provided...

Figure 4. Human RBCs contain an active NOS. (A) Constitutive NOS (135 kDa) was isolated from human RBCs by affinity chromatography with a calmodulin (CaM)-binding column followed by immunoprecipitation (IP) with a mouse anti-human NOS3 or directly by immunoprecipitation from crude RBC lysates (lanes 1 and 2, as well as 3 and 4 are independent samples). (B) The NOS enzyme was isolated directly from crude red cell lysates by immunoprecipitation with a mouse anti-human eNOS antibody and analyzed by Western blotting. As a control a crude EC lysate was loaded in lane 5 (MWM indicates molecular weight marker). (C) Coomassie gel used for identification purposes and representative example of peptide identification by LC-MS/MS sequencing; depicted is the fragmentation spectrum of the peptide AQSQAQQGLR. (D) Alignment of peptides identified by LC-MS/MS with sequences of nNOS, iNOS and all known eNOS splice variants. Top panel: Peptides 1 and 2 aligned within the FMN reductase-like region (FMN binding region), whereas peptides 3 and 4 aligned with the ferredoxin reductase (FRN-like) region (FAD and NADPH binding region). CysJ indicates sulfite reductase, α subunit (flavoprotein) region. NOS oxygenase indicates nitric oxide synthase eukaryotic oxygenase domain. Bottom panels: The sequences shown in detail and compared with the other NOS isoforms. The sequences of the peptides are identical with NOS3, isoform 1 only. NP_000611 = NOS1, nNOS; NP_000594 = NOS2, iNOS; NP_000594 = NOS3, isoform 1. Splice variants of NOS3 are NP_001153581 = NOS3, isoform 1, NP_001153582 = NOS3, isoform 3, NP_001153583 = NOS3, isoform 4. (E) Activity of a red cell NOS may be involved in the regulation of RBC lifespan, deformability, potentially red cell velocity and blood flow. This notion is in line with previous findings showing that NOS inhibitors abolish the antiplatelet effects of RBCs in vitro and decrease the level of NO products released by isolated RBCs, however they do not affect intracellular nitrite concentrations. Thus RBCs may also contribute to vascular homeostasis, independent of their “classic role” as transporters of oxygen, energy substrates and nutrients. Given the contribution RBCs make to the circulating NO pool and their role in hypoxic vasodilation further studies are warranted to address its functional significance for the regulation of RBC function and beyond.
protein with eNOS epitopes. Two groups hypothesized that RBCs express a novel NOS isoform,23,25 but no sequence confirmation analysis was provided.

The main technical hurdle in the biochemical characterization of proteins in RBCs is the presence of overwhelmingly high level of hemoglobin, which represents a formidable obstacle to purification, activity determination, immunostaining, and colorimetric/fluorimetric assay. In this study, we chose to isolate NOS from hemolysates under native conditions to permit combined structural and functional analysis. After purification of calmodulin-binding enzyme by affinity chromatography and immunoprecipitation using anti-eNOS antibodies, we identified a 135 kD-band by SDS-PAGE, indicating that red cell NOS contains both a calmodulin binding site and eNOS-like epitopes. Similar results were obtained when immunoprecipitation was performed directly from crude RBC lysates using different antibodies. Although these results strongly suggested that the 135 kD band isolated from RBCs was indeed an eNOS protein, further analyses were performed to obtain peptide sequences of tryptic digests by LC-MS/MS. Obtaining the sequence of 4 different peptides from 2 independent analyses permitted unequivocal identification of the protein as the classic eNOS (NOS3) isoform. Two of the 4 sequenced peptides aligned with 100% homology to the C-terminal region of eNOS, whereas one peptide was aligned with 100% homology to the NOS3A-C splice variants. Less homology was observed with the sequences related to nNOS (NOS1) and iNOS (NOS2). We thus conclude that RBCs contain eNOS, the same protein that is constitutively expressed in endothelial cells. Two earlier studies suggested that RBCs also contain iNOS.23,25 We are unable to confirm these reports as we failed to isolate any iNOS from crude human RBC lysates of healthy donors using specific anti-iNOS antibodies for immunoprecipitation.

Although a L-NNA/L-NAME-inhibitable NOS activity was dependent on the presence of Ca2+ in our study was catalytically active, L-arginine:citrulline conversion was observed from crude human RBC lysates of healthy donors using specific antibodies. Although these results strongly suggested that the 135 kD band isolated from RBCs was indeed an eNOS protein, further analyses were performed to obtain peptide sequences of tryptic digests by LC-MS/MS. Obtaining the sequence of 4 different peptides from 2 independent analyses permitted unequivocal identification of the protein as the classic eNOS (NOS3) isoform. Two of the 4 sequenced peptides aligned with 100% homology to the C-terminal region of eNOS, whereas one peptide was aligned with 100% homology to the NOS3A-C splice variants. Less homology was observed with the sequences related to nNOS (NOS1) and iNOS (NOS2). We thus conclude that RBCs contain eNOS, the same protein that is constitutively expressed in endothelial cells. Two earlier studies suggested that RBCs also contain iNOS.23,25 We are unable to confirm these reports as we failed to isolate any iNOS from crude human RBC lysates of healthy donors using specific anti-iNOS antibodies for immunoprecipitation.

Is red cell eNOS of relevance to cardiovascular disease?

Perhaps one of the most surprising results from our studies is that red cell eNOS expression and activity significantly correlate with flow-mediated dilation, a diagnostic marker of endothelial function and eNOS activity. Similarly to endothelial eNOS dysfunction, red cell eNOS dysfunction may depend on both decreased protein levels, and changes in regulation/catalytic activity. Impaired endothelial function, decreased eNOS activity, and/or NO bioavailability are conditions strongly related to cardiovascular disease.26,46 Thus, a systemic eNOS deficiency and/or dysfunction appears to prevail in patients with cardiovascular disease the consequences of which are not limited to impaired vascular function, but may also affect function of platelets47 and red blood cells.

A central challenge of any hypothesis proposing a role of RBC-derived NO in human (patho)physiology is to understand how NO formed by these cells can escape irreversible dioxygenation reaction with oxyhemoglobin, a rapid reaction known to convert NO to nitrate. A “metabolon complex” of deoxyhemoglobin, AE/band 3, carbonic anhydrate, aquaporin, and Rh-protein channels was proposed to explain nitrite protonation and may serve to facilitate the export of NO or its metabolites.58 The localization of eNOS-immunoreactivity on the cytoplasmic side of the RBC membrane, as detected by immunogold-labeling and electron microscopy imaging,66 supports the notion that the RBC membrane plays a central role in this process, possibly by effectively “compartmentalizing” NO production, signaling and scavenging machinery. Our results invite a rethink about the role of hemoglobin in NO biology, because its oxygenated form is considered an NO scavenger under any condition. Several factors have been identified that explain why endothelial NO escapes scavenging by hemoglobin,8,11,45,48,49 but those discussions did not consider the possibility that NO might be produced in RBCs themselves. The observation that NO formation can be detected in the vicinity of abundant oxyhemoglobin would seem to warrant a careful reassessment of this universally accepted paradigm.

Summary and outlook

Only recently indices of RBC number, size, and function have emerged as independent risk factors of cardiovascular disease.1-3 Not only endothelial cells, but also RBCs may contribute to NO-dependent regulation of vascular homeostasis. Our present findings suggest that red cell eNOS activity might serve the purpose of compensating for NO trapping by providing an efficient “NO shield” that maintains effective intracellular signaling. Moreover, red cell eNOS expression/activity might be a complementary diagnostic tool to assess vascular homeostasis and provide new therapeutic strategies for fighting cardiovascular disease.

Acknowledgments

The authors thank Katharina Lysaja for indispensable technical assistance; Profs Victoria Kolb-Bachofen, Dieter Häussinger, and Jeremy Spencer for allowing them to use the FluostarOPTIMA, the FACS Canto II flow cytometer, and the HPLC, respectively; and Prof Axel Gödecke for offering the use of his radioisotope facility. This work was supported by the Deutsche Forschungsgemeinschaft (DFG 405/5-1 and FOR809 TP7 Me1821/3-1), the Anton Betz Stiftung, (26/2010), the Susanne Bunnenberg Stiftung at Duesseldorf Heart Center to M.K., and the Forschungskommission of the Medical Faculty of the Heinrich Heine University of Duesseldorf to M.M.C.-K. LC-MS analyses were conducted at the Chemical Analytical Facility, University of Reading.
