Primary central nervous system lymphoma (PCNSL) treatment includes 2 phases: induction and consolidation. Induction consists of high-dose methotrexate–based polychemotherapy for most patients, with regimen and dose variations according to patient characteristics and country. Several strategies have been proposed for the consolidation phase, with whole-brain irradiation (WBRT) the most common. However, some authorities recommend avoiding WBRT because of its related risk of severe neurotoxicity. The most relevant alternatives to WBRT are high-dose chemotherapy supported by autologous stem cell transplantation (HDC/ASCT) or nonmyeloablative chemotherapy, the former supported by several single-arm phase 2 trials. Moreover, HDC/ASCT is the only strategy that is assessed in comparison with WBRT in ongoing randomized trials. The rationale for using HDC/ASCT in PCNSL patients is based on the fact that the delivery of high doses could achieve therapeutic drug concentrations in the brain and cerebrospinal fluid, and that non–cross-resistant drugs used for conditioning (eg, alkylating agents) could favor elimination of residual chemoresistant lymphoma cells. Worldwide experience with HDC/ASCT is limited to few single-arm phase 2 trials, but overall results are encouraging, mostly when thiotepa-containing conditioning regimens are used, both in newly diagnosed and relapsed patients. However, several questions on efficacy and feasibility of HDC/ASCT, as well as the best candidates for this strategy, the optimal conditioning regimen, the best time for response assessment, and acute and late effects, remain unanswered. In this review, we critically analyze reported studies on HDC/ASCT in PCNSL and discuss its current role and future perspectives in treating this aggressive malignancy. (Blood. 2016;127(13):1642-1649)

Introduction

Primary central nervous system lymphoma (PCNSL) is an aggressive malignancy occurring exclusively in the central nervous system (CNS) (ie, the brain parenchyma, spinal cord, eyes, cranial nerves, and/or meninges).1 It represents 4% of intracranial neoplasms and 4% to 6% of all extranodal lymphomas, exhibits peculiar clinical and biological features, and constitutes a diagnostic and therapeutic challenge for multidisciplinary clinicians and scientists.2 Its outcome remains unsatisfactory if compared with that of extra-CNS lymphoma patients at a similar stage and histology, and several factors prevent therapeutic progress. In particular, PCNSL patients often show impaired general conditions and poor performance status (PS),3 which interferes with patients enrollment in prospective trials. Current therapeutic knowledge is only based on 4 reported randomized trials, few single-arm phase 2 trials, and some multicenter retrospective studies. This low level of available evidence induces consequent uncertainties in therapeutic decisions and lack of consensus on primary end points for future trials. Moreover, molecular and biological knowledge is insignificant compared with other lymphomas, which limits the identification of new therapeutic targets.

The treatment of PCNSL currently consists of 2 phases: induction and consolidation. Induction consists of high-dose methotrexate (HD-MTX)–based polychemotherapy for most patients, with regimen and dose variations according to age, PS, comorbidity, and geographic area.4 Several strategies have been proposed for the consolidation phase, with whole-brain irradiation (WBRT) among the most common. However, increased risk of severe neurotoxicity, especially in elderly patients, has been reported with chemo-radiation therapy.5 Recent international efforts have focused on establishing valid alternatives to consolidative WBRT, mostly consisting of high-dose chemotherapy supported by autologous stem cell transplantation (HDC/ASCT)6 or nonmyeloablative chemotherapy.7 HDC/ASCT is supported by several single-arm phase 2 trials and is the only one that is compared with WBRT in ongoing randomized trials. In this review, we critically analyze reported studies on HDC/ASCT in PCNSL and discuss its potential role and future perspectives in the treatment of this poor-prognosis malignancy.

Background and rationale

For decades, WBRT alone was the standard treatment of PCNSL, with both high response and relapse rates. Almost all patients treated with WBRT alone experience relapse within the first year of follow-up. Although the addition of chemotherapy has remarkably improved PCNSL patients’ outcomes, the cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP) regimen, the most commonly used chemotherapy combination in diffuse large B-cell lymphomas (DLBCLs), has not resulted in improved survival compared with WBRT alone.8 Better results have been progressively reported with a wider use of HD-MTX–based polychemotherapy induction in combination with consolidative WBRT.9 A parallelism with the management of limited-stage, extra-CNS DLBCL can be made. In the prerituximab era, anthracycline-based chemotherapy followed by

involved-field radiotherapy was the standard treatment in limited-stage DLBCL. With a wider use of rituximab, and 18fluorodeoxyglucose positron emission tomography (PET) in particular, the role of consolidative radiotherapy in extra-CNS DLBCL was constrained, even if randomized trials focused on this issue in the rituximab era do not exist.10 This is mostly because of better disease control with immunochemotherapy and an improved definition of response degree in patients with residual masses at computed tomography scan. Accordingly, postchemoimmunotherapy 18fluorodeoxyglucose-PET allows us to identify DLBCL patients with metabolic complete response, who can be successfully managed without consolidative radiotherapy. Similarly, a growing inclination to avoid radiotherapy in patients achieving complete remission (CR) after induction chemotherapy has been applied also to PCNSL.11 This choice is strongly motivated by the previously mentioned association between WBRT and risk of severe neurotoxicity.5 However, WBRT withdrawal should be considered with caution as the situation is completely different in PCNSL, where the quality of response after chemotherapy is suboptimal compared with DLBCL patients treated with rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone (R-CHOP). Moreover, quality of response assessment is worse in PCNSL as PET is not currently used and magnetic resonance imaging shows relevant limitations. Most PCNSL patients treated without WBRT experience relapse, and only a small proportion of failed patients benefit from salvage treatment,12 which has not changed with a wider use of rituximab. Two schools of thought were therefore established. On the one hand, some authorities believe that WBRT should remain the standard of care in routine practice, at least until results from randomized trials comparing WBRT with HDC/ASCT are available.13 On the other hand, some experts are convinced that the level of evidence supporting up-front HDC/ASCT is sufficient to recommend the use of this strategy in routine practice. Guidelines from the European Association of Neuro-Oncology consider up-front HDC/ASCT as an experimental treatment in PCNSL,4 whereas National Comprehensive Cancer Network guidelines for routine practice refer to HDC/ASCT as an alternative to WBRT in patients who achieve CR after HD-MTX-containing induction.14

The use of HDC/ASCT in PCNSL is based on its efficacy in recurrent systemic lymphoma. PCNSL manifests in a sanctuary behind the blood-brain barrier (BBB), escaping control from the host immune system and exposure to most conventionally dosed cytotoxic drugs. With the exception of some lipophilic drugs that successfully penetrate the BBB at conventional doses,15 most other drugs must be administered at high doses to achieve cytotoxic concentrations in the brain tissue and cerebrospinal fluid,16 which constitutes part of the rationale for the use of HDC/ASCT in PCNSL. In addition, non–cross-resistant drugs used for conditioning (eg, alkylating agents) increase the possibility of eliminating residual lymphoma cells that may be resistant to drugs used for induction. A few single-arm phase 2 trials and retrospective studies have shown encouraging outcomes with HDC/ASCT in patients with PCNSL both as up-front and salvage treatment (Table 1).6,18,26,29,30 Most trials addressing HDC/ASCT included a small number of patients, often with a short follow-up period, and series showed differences in patient and lymphoma characteristics and therapeutic management. Thus, several questions on its efficacy and feasibility, as well as the best candidates for this strategy, the optimal conditioning regimen, the best time for response assessment, and acute and late effects, remain unanswered. In addition, one of the main reasons to use consolidative HDC/ASCT instead of WBRT is a putative reduction of the risk of severe neurotoxicity. However, it is important to underline that, with a single exception,26 a formal neurotoxicity assessment through validated neuropsychological tests has not been performed in retrospective and prospective studies. Thus, reported neurotoxicity rates regard patients with evident neurologic symptoms attributed to therapeutic side effects (Table 1), with a consequent underestimation of the incidence of this complication. Accordingly, neurocognitive safety of HDC/ASCT remains to be formally demonstrated.

### ASCT as salvage therapy

Since the first report of durable remission obtained with HDC/ASCT in a patient affected by relapsed PCNSL,31 this approach has been used in explorative series and prospective trials on patients with PCNSL. HDC/ASCT was first used in patients with relapsed refractory PCNSL more than 20 years ago in France, especially among patients with relapsed intraocular lymphoma, and it was subsequently applied to every patient with recurrent PCNSL.13 Twenty-two patients, half of them with relapse limited to the eyes, were treated with 2 courses of cytarabine-etoposide combination, and patients with chemosensitive lymphoma were treated with a combination of thiopeta, busulfan, and cyclophosphamide followed by ASCT (Table 1). CRR after the full treatment was 80%, with grade 4 neutropenia and thrombocytopenia in all patients, septic complications in 86% of cases, and 23% TRM, mostly among patients >60 years old.13 With this strategy, the 3-year event-free survival (EFS) and OS were 53% and 64%, respectively. Outcome was evidently different among patients with failure limited to the eyes compared with the remaining patients, with a median OS of 33+ months and 12 months, respectively.13 Discrepancies in outcome between these subgroups suggest biological differences and a potential selection bias. Importantly, 32% of patients developed neurologic toxicity, which was fatal in one-third of the affected patients. This complication, consisting of severe chronic leukoencephalopathy with cognitive dysfunction, had been equally observed both in patients >60 years old who did not receive WBRT and in previously irradiated younger patients.

Despite important TRM and risk of neurotoxicity, these results led the same authors to conduct a second phase 2 trial on relapsed/refractory patients, treated according to the same strategy already described.18 In this trial, 43 PCNSL patients (median age, 52 years) with relapse (n = 22), refractory disease (n = 17), or partial response to first-line treatment (n = 4) were enrolled. Patients with failure limited to the eyes constituted only 14% of cases. CRR after the full treatment was 60%, with expected hematologic toxicity and 16% TRM. Severe neurotoxicity was observed in 12% of cases, but this rate is probably underestimated considering that prospective neuropsychological assessment had not been performed and that many patients dying early because of lymphoma or toxicity had been considered as censored for this analysis. With a median follow-up of 36 months, the 2-year OS was 45%. Interestingly, 12 patients with stable or progressive disease after induction chemotherapy had been referred to HDC/ASCT obtaining transient CR in 11 cases, with a median progression-free survival (PFS) of 9 months.18 Chemosensitivity, defined as objective response to induction chemotherapy, was independently associated with better outcomes.

These results compare favorably with other conventional-dose salvage treatments used both as mono- and polychemotherapy. In fact, median PFS and 2-year OS were 10 to 15 months and 33% for topotecan,12 3 months and 21% for temozolomide,33 and 26 months and 70% (1-year OS) for HD-MTX retreatment.34 Salvage polychemotherapy was associated with median PFS of 5 months and 1-year OS of 41%.35 However, these trials included patients selected by using less restrictive criteria compared with PCNSL trials testing salvage HDC/ASCT. This is of crucial importance if we consider that only 40% of
patients <70 years old with relapsing/refractory PCNSL currently receive HDC/ASCT.\(^{19}\) The gap in results with conventional-dose salvage and HDC/ASCT are less impressive when comparing similarly selected populations. Moreover, the promising results yielded with salvage HDC/ASCT should be taken into account with caution considering that this strategy is associated with relevant TRM and severe neurotoxicity in elderly or previously irradiated patients. Although it was not addressed in well-designed prospective trials, our experience shows that patients with relapsed PCNSL are more frail than other lymphoma patients referred to salvage ASCT and exhibit higher rates of fatal complications both during induction therapy and ASCT. Poor PS and severe neurologic deficits often result in prolonged immobilization, with consequent higher rates of deep venous thrombosis, pulmonary embolism, and septic complications. These major concerns suggest that this strategy should be used carefully out of well-designed clinical trials, and recent, small retrospective series managed with thiotepa-based conditioned/ASCT showed that adequate selection of candidates is associated with excellent feasibility and safety profiles and encouraging survival figures.\(^ {19,36}\)

# ASCT as up-front treatment

## Induction chemotherapy regimens

With anecdotal exceptions, only patients with PCNSL responsive to induction phase are referred for HDC/ASCT. Accordingly, the choice of induction treatment is extremely important both to achieve high response and autologous stem cell (ASC) collection rates, with the obvious consequence to offer HDC/ASCT to a higher proportion of treated patients.

All prospective trials reporting on HDC/ASCT in the first-line setting used different variations of HD-MTX as induction treatment, reflecting the heterogeneity across study groups and countries of treatment approaches in newly diagnosed PCNSL. In this setting, HD-MTX was used as a single agent, as part of sequential programs, and included in polychemotherapy combinations. HD-MTX monotherapy, at a dose of 8 g/m\(^2\), was used in a single trial\(^ {25}\); CRR after induction was 13%, and 69% of patients proceeded to HDC/ASCT, most of them with residual disease at transplantation. Sequential protocols mostly used combinations of HD-MTX and high-dose cytarabine (HD-ARAC). A combination of 5 biweekly HD-MTX (3.5 g/m\(^2\)) cycles followed by 2 monthly courses of HD-ARAC (2 × 3 g/m\(^2\)) resulted in 50% of patients proceeding to HDC/ASCT.\(^ {20,23}\) Two prospective German studies addressed a sequential induction before HDC/ASCT\(^ {24,25}\); CRR was 15% after induction with HD-MTX (8 g/m\(^2\)), 27% after intensification with HD-ARAC (2 × 3 g/m\(^2\)) and thiotepa (2 × 5 mg/kg) combination, and 77% after HDC/ASCT.\(^ {25}\) This observation suggests that HDC/ASCT is active per se, resulting in encouraging outcomes, even among patients with residual disease at the time of conditioning.

The most encouraging results were reported with HD-MTX (3 or 3.5 g/m\(^2\)) in combination with alkylating agents (ie, carmustine, procarbazine, thiopeta) and/or HD-ARAC. These polychemotherapy combinations have resulted in high ASC mobilization rates and CRR of up to 66%, with up to 81% of patients proceeding to ASCT\(^ {21,26}\) (Table 1). The anti-CD20 monoclonal antibody rituximab is another important component of induction treatment. As salvage monotherapy, rituximab has been associated with an overall response rate (ORR) of 42%,\(^ {37}\) and its combination with HD-MTX–based chemotherapy is feasible,\(^ {38}\) but there are many doubts about its capability to cross the BBB.\(^ {39}\) A few retrospective studies using historical controls suggested that the addition of rituximab is associated with improved response rates, but effect on survival is unclear because of the small number of patients and follow-up duration imbalances.\(^ {40,41}\) Recently, results from the first randomization of the International Extranodal Lymphoma Study Group (IELSG) 32 trial aimed to establish the most active induction regimen were presented.\(^ {42}\) The combination of HD-MTX, HD-ARAC, thiopeta, and rituximab (called MATRIX regimen) was associated with an ORR of 87% and a 2-year PFS of 62%\(^ {42}\); as for other HD-ARAC-based combinations,\(^ {21}\) MATRIX allows successful ASC collection in 94% of cases.

With the limitations of comparison among single-arm phase 2 trials, available literature suggests that HD-MTX–based polychemotherapy should be preferred to monotherapy or sequential programs as pre-ASCT induction. Higher toxicity is compensated with high response
and ASC collection rates. Although randomized trials comparing different induction regimens containing HD-MTX, alkylating agents, and rituximab do not exist, we suggest using MATRIX regimen as standard induction approach to patients ≤70 years old with newly diagnosed PCNSL because it is the sole induction regimen addressed in a randomized trial and is supported by the highest level of evidence in this field.

Conditioning regimens

**BEAM regimen.** BEAM (Table 2) is the most commonly used conditioning regimen in patients with relapsed or refractory DLBCL.20 Because of its well-known feasibility, safety profiles, and efficacy, it was one of the first conditioning combinations used in PCNSL.20,22 When the most consistent trials were considered, median time to engraftment after BEAM was 8 days for neutrophil recovery ≥500/μL and 9 days for platelet recovery ≥2,000/μL,20,21 which is not significantly different to engraftment after thiopeta-based conditioning.29 Toxicity after BEAM was intermediate between those reported after the combination of high-dose busulfan and thiopeta and after BCNU-thiopeta conditioning,6,29 with a TRM of 13% in patients treated with high-dose busulfan-thiopeta combination;4% after BEAM,20,21 and 0% after BCNU-thiopeta conditioning;6,29 TRM is currently attributed to the frequent and prolonged immobilization of PCNSL patients, recurrently associated with pulmonary embolism and fatal pneumonia.25

Two trials addressed a HD-MTX–based induction followed by BEAM-conditioned ASCT.20,21 In a French multicenter prospective trial,21 25 patients with newly diagnosed PCNSL were administered 2 courses of MVBP regimen (HD-MTX, carmustine, etoposide, and melphalan).45 Therefore, disappointing results and CNS bioavailability of the HD-MTX-based chemoimmunotherapy, with 81% of patients receiving intrathecal chemotherapy and WBRT, which prevents drawing definitive conclusions on the effect of BEAM on survival. The only phase 2 trial addressing BEAM-conditioned ASCT in a radiotherapy-free program was a monoinstitutional experience from the Memorial Sloan Kettering Cancer Center.27 In this trial, a sequential combination of high doses of MTX and ARAC followed by BEAM/ASCT resulted in 57% ORR after induction, with half of enrolled patients receiving ASCT. Even in this trial, contribution of BEAM regimen to response rate was modest, with a median EFS of only 9 months and a 2-year OS of 60%; 57% of transplanted patients experienced relapse within the first 6 months of follow-up, whereas late relapses were not recorded because follow-up of survivors was usually shorter than 3 years.20,21

Overall results obtained with BEAM-conditioned ASCT are unsatisfactory, which could be explained at least in part by the low capability to cross the BBB of drugs included in this combination. In fact, although drugs used in other conditioning regimens, such as busulfan, thiopeta, and BCNU, have excellent CNS penetration, with cerebrospinal fluid levels in excess of 80% serum levels for busulfan and thiopeta, and of 50% to 80% for BCNU, CNS penetration rates for agents in the BEAM regimen are very low, such as 5% for etoposide, 6% to 22% for ARAC, and 10% for melphalan.45 Therefore, disappointing results and CNS bioavailability data led most specialists to abandon BEAM as conditioning regimen in the first-line treatment of PCNSL.

**Busulfan-thiopeta regimens.** Different combinations of high doses of busulfan and thiopeta, with or without other drugs, have been used as conditioning regimen in some PCNSL series (Table 2). Busulfan and thiopeta are 2 drugs with excellent CNS bioavailability and a good profile of nonhematologic toxicity. The use of busulfan-thiopeta combination after single-agent MTX 8 g/m² in PCNSL patients 18 to 65 years old has been associated with an 83% ORR, but feasibility has been suboptimal, with less than half of the patients receiving full treatment, and a 2-year OS of 48%,25 which seems to be related to a poor quality response to induction therapy. Importantly, TRM was 13%, and an additional 10% of patients died of severe neurotoxicity.25 Busulfan-thiopeta regimen has often been used in combination with high-dose cyclophosphamide (TBC regimen: thiopeta, 250-300 mg/m² per day, days –8 to –7; busulfan, 3,2-9.6 mg/kg BW/d, days –6 to –4; cyclophosphamide, 2 g/m² per day, days –3 and –2) in PCNSL patients (Table 1). Preliminary studies on TBC combination were performed on small and heterogeneous retrospective series, sometimes combining patients with PCNSL and secondary CNS lymphoma, as well as with untreated and relapsed disease, with consequent difficulties to interpret results.27,28,36,43 In the largest retrospective series, the 5-year OS of patients treated with HD-MTX-based induction followed by TBC-conditioned ASCT was 44%.27 Post-ASCT relapses displayed notable aggressiveness and chemoresistance. In a recent phase 2 trial,32 32 PCNSL patients were treated with HD-MTX–based chemimmunotherapy, with 81% of...
responders performing TBC-ASCT (thiotepa, 250 mg/m² per d, days
−9, −8, and −7; busulfan, 3.2 mg/kg per d, days −6, −5, and −4;
cyclophosphamide, 60 mg/kg per d, days −3 and −2). Assessment
by formal neuropsychological tests showed significant improvement
in some cognitive functions, with no evidence of neurologic decline.
At a median follow-up of 45 months, the PFS and OS were 81%, but
these encouraging results should be considered cautiously, with only
19% of the study group having high risk scores. Overall, these
studies have suggested TBC regimen is active in patients with
newly diagnosed PCNSL responsive to HD-MTX–based induc-
tion, but toxicity remains a major concern. In fact, a median
length of hospital stay of 24 to 28 days, median time to neutrophil
and platelet recovery of respectively 9 and 13 days have been
reported. Importantly, septic complications, mostly bacterial
infections, occur in one-third of treated patients, with grade
≥3 febrile neutropenia in 42% of patients, grade ≥3 infections in
23%, nonrelapse mortality of up to 24%, and a TRM of up to 19%.
These complications are more common among patients older than 60
years, but, overall, these rates seem to be higher than those with other
thiotepa-based regimens (see “BCNU-thiotepa regimens”). Grade 3 to
4 mucositis is a major complication, reported in up to 81% of treated
patients, with 16% requiring total parenteral nutrition. More specific
complications, like hemorrhagic cystitis, prolonged noninfectious
diarrhea (15%), cholestasis, rash and other skin toxicities, reversible
acute neurotoxicity (delirium, ataxia, dysphagia, weakness in 22% of
cases), and peripheral edema have often been reported with TBC regimen.
TBC regimen needs adjunctive therapy including multiple daily showers
during thiotepa treatment, and delivery of phenytoin or lorazepam and
mesna to prevent some of these toxicities. Accordingly, TBC is an effective conditioning regimen, but its
use should be restricted to experienced centers because of related
toxicity.

**BCNU-thiotepa regimens.** Two German phase 2 trials addressed BCNU-thiotepa combination as conditioning in PCNSL
patients. Patients under 65 years old were managed with sequential induction chemotherapy, including 3 cycles of HD-
MTX (8 g/m²) and HD-ARAC-thiotepa combination. In the first trial, thiotepa dose at conditioning was 5 mg/kg body weight, and
all patients received WBRT. This conditioning regimen was well
tolerated, with no relevant acute or late extrahematologic toxicity, with the exception of grade 1 to 2 mucositis in 26% of transplanted
patients. At a median follow-up of 63 months, the 5-year OS was
69% for all patients and 87% for those completing HDC/ASCT. In
the second trial, induction chemotherapy was intensified, the
thiotepa dose doubled, and only those patients who did not achieve CR after induction therapy underwent WBRT. Importantly,
CRR after induction was 31%, whereas CRR after ASCT stood at 85%, demonstrating that BCNU-thiotepa combination is active per se, suggesting an excellent CNS bioavailability and non–cross-resistant efficacy. Likewise, an increase in CRR after ASCT has been reported in a phase 2 trial on American patients managed with TBC regimen. Interestingly, survival curves of patients with pretransplantation CR or partial response were similar in a retrospective study that analyzed patients with PCNSL and SCNSL together. These figures contrast with National Comprehensive Cancer Network guidelines that recommend ASCT only for PCNSL patients who achieve CR after HD-MTX–based induction therapy. Although based on a small number of treated patients, cumulative evidence suggests that thiotepa-conditioned ASCT should be offered even to patients with partial response after induction treatment.

BCNU-thiotepa-conditioned ASCT was generally well tolerated, no patients died of toxicity, and increased dose of thiotepa did not result
in increased side effects. The 3-year OS was 77%, and CRs achieved
long-term remission without WBRT, suggesting a potential curative
effect. Similar encouraging results have been reported in small case
series treated in other countries. BCNU-thiotepa-conditioned ASCT
was used, following MTRIx induction in 5 HIV-related PCNSL
patients, resulting in lymphoma remission longer than 2 years in 2
patients. Overall, HDC/ASCT should be used with caution in
HIV-positive patients with PCNSL because of the high risk of fatal
complications. However, this strategy merits further evaluation
in these high-risk subgroup of patients, mostly to identify the best
candidates and establish the best conditioning regimen.

Currently, BCNU-thiotepa regimens seem to be the best compromise
between safety and efficacy as conditioning regimens in patients
with newly diagnosed PCNSL.

**Thiotepa-free regimens other than BEAM.** To date, 2 thiotepa-
free conditioning regimens other than BEAM have been explored in
patients with newly diagnosed PCNSL (Table 1). Both regimens were
assessed in small retrospective series of Asian patients. BUCYE
regimen (busulfan, 3.2 mg/kg per d, days −7 to −5; cyclophospha-
hide, 50 mg/kg per d, days −3 and −2; etoposide, 200 mg/m²,twice
day, days −5 and −4) was tested after induction with sequential high-
dose MTX and ARAC in 11 Korean patients with PCNSL. This regimen
was associated with grade 3 diarrhea in 2 patients and febrile
neutropenia in 10; no patients died of toxicity. All patients achieved
CR before ASCT, and 6 out of 8 patients with a follow-up of >1 year
experienced relapse; at a median follow-up of 25 months, EFS was 30%
(median, 15 months) and OS was 89%. However, these results should
be considered with caution because treated series was small, follow-up
was short and salvage therapy showed a remarkably positive effect.
Overall, these results are similar to those reported with BEAM and
appear inferior to that reported with thiotepa-based regimens (see
“Busulfan-thiotepa regimens” and “BCNU-thiotepa regimens”).
LEED conditioning regimen (cyclophosphamide, 60 mg/kg per d,
days −4 and −3; etoposide, 250 mg/m² every 12 hours, days −4 to −2;
melphalan, 130 mg/m² once daily on day −1; dexamethasone, 48 mg/d,
days −4 to −1) was tested after induction with sequential MVP and
HD-ARAC in 13 Japanese patients with PCNSL. In spite of good
initial response rate, only half of the patients received ASCT. All
transplanted patients achieved engraftment, and there were no toxic
deaths. Actuarial survival figures were encouraging (3-year OS, 75%);
and, conversely to those reported in all the other ASCT studies in this
field, transplanted and not transplanted patients showed similar survival
(3-year OS, 80% vs 71%; P = .05). Actually, the small number of
transplanted patients and the use of WBRT in more than half of patients
render this preliminary experience hard to interpret.

**Ongoing trials**

Large ongoing trials in PCNSL patients are mostly focused on
improving activity of induction combinations and enhance efficacy of
consolidation treatment, both following the main goal to reduce
overall toxicity, late neurotoxicity in particular. Four large, ongoing
randomized trials aim to compare HDC/ASCT with WBRT or with
nonmyeloablative chemotherapy as consolidation treatment. The
first 2 compare the effect of HDC/ASCT and WBRT as consolidation
after HD-MTX–based polychemotherapy in patients with newly
diagnosed PCNSL. The accrual of the IELSG32 trial (#NCT01011920)
was recently completed; 227 patients were enrolled in 53 centers in
5 European countries. The trial consisted of a double randomization addressing the effect of the addition of rituximab and/or thiopeta at high doses of MTX and ARAC in the first randomization and addressing WBRT and HDC/ASCT as consolidation in the second comparison. CRR and PFS are the primary end points of the first and second randomizations, respectively. Preliminary results suggest increased activity with the addition of both rituximab and thiopeta, and more mature data on the second randomization are expected next year. PRECIS (#NCT00863460) is a French multicenter randomized phase 2 trial comparing the same chemoimmunotherapy (sequential high-dose MTX and ARAC-based chemotherapy plus rituximab) followed by WBRT or HDC/ASCT, with 2-year PFS as primary end point. The IELSG32 and PRECIS trials could provide different results as they vary in design and patient selection. In particular, the upper age limit is 60 years in the PRECIS trial and 70 years old in the IELSG32 trial; randomization was performed at trial registration in the PRECIS trial and only after confirmation of response to induction chemotherapy in the IELSG32 trial; and conditioning regimens are different: TBC in the PRECIS trial and BCNU-thiopeta in the IELSG32 trial. Although these relevant differences should be considered cautiously at results interpretation, both trials will provide relevant conclusions on the role of HDC/ASCT and will establish the subgroup of PCNSL patients as the best candidates for this intensified strategy.

Based on the encouraging results of the Alliance/CALGB 50202 trial, this American Intergroup is performing a multicenter randomized phase 2 trial that compares BCNU-thiopeta-conditioned ASCT and nonmyeloablative combination of high doses of etoposide and ARAC (etoposide, 40 mg/kg continuous IV over 96 hours, days 1-4; ARAC 2 g/m² IV over 2 hours, every 12 hours, for 8 doses, days 1-4) in 160 patients 70 years old with PCNSL responsive to induction combination of methotrexate, temozolomide, and rituximab (#NCT01511562). A similar international trial sponsored by the IELSG (IELSG43) compares BCNU-thiopeta-conditioned ASCT with conventional-dose ifosfamide-based chemotherapy as consolidation in 250 patients with PCNSL responsive to MATRrix chemoimmunotherapy (#NCT02531841). As an overall strategy, these randomized trials will establish the best consolidative strategy as part of first-line treatment in PCNSL patients but, at the same time, will suggest which of these strategies could be kept to consolidate responses to chemotherapy in patients with relapsed/refractory disease. This is an important aspect considering that failed patients often achieve response to salvage chemotherapy. This is often short-lived, mostly because of the unavailability of feasible and effective consolidative strategies.

Open questions for future trials

Based on available evidence, HDT/ASCT is associated with high remission rates and excellent long-term outcomes in eligible patients. As outlined previously, several important questions are currently being addressed in ongoing randomized trials. However, many unanswered questions remain, in particular, the establishment of the best candidates for up-front ASCT. In current practice, only young patients, without relevant comorbidity, with preserved neurocognitive functions, and chemosensitive lymphoma are referred to HDC/ASCT as part of first-line treatment. Patients with these characteristics represent only a part of PCNSL population. In fact, the proportion of enrolled patients in prospective trials that are successfully referred to HDC/ASCT oscillated between 46% and 81%, with higher rates among patients younger than 65 years (Table 1). Unfortunately, HDC/ASCT will hardly contribute to improve outcome in elderly patients. There is currently no consensus on the upper age limit to define “elderly patients” in the field of PCNSL and to identify patients eligible for HDC/ASCT. This strategy is not advised for patients older than 65 years in some institutions, whereas it is proposed to selected patients older than 70 years in others. Thus, it is conceivable that most patients older than 70 years and a good proportion of those older than 65 are not referred to ASCT, which is an important limitation as alternative to WBRT considering that the most relevant actinic toxicity is observed in this subgroup of patients. Because both ASCT and WBRT may be associated with unacceptable toxicity, other consolidative strategies, like maintenance with immunomodulators or cytostatics, should be assessed in elderly PCNSL patients. The establishment of molecular and imaging markers able to distinguish the best candidates for HDC/ASCT is an important issue. For instance, the predictive effect of early magnetic resonance imaging assessment and brain PET deserve further investigation in this setting. A wider use of reliable prognostic factors (eg, IELSG score) may also result in personalized induction treatment, with a consequent better patient selection, improved feasibility, and a higher proportion of patients being referred to consolidate ASCT. Although available evidence, exclusively provided by single-arm phase 2 trials, seems to support higher efficacy and better tolerability of BCNU-thiopeta combination, the best conditioning regimen remains to be established as randomized comparisons among different myeloablative combinations do not exist. Finally, salvage ASCT used in anecdotal cases of PCNSL relapsed after up-front ASCT should be further investigated as a valid option to avoid the use of consolidation WBRT and its related neurotoxicity. The number of available effective therapeutic tools against PCNSL is progressively increasing. ASCT will play a central role in the near future, hopefully as part of up-front and salvage therapies. International efforts should be focused on improving feasibility and efficacy of this important strategy.

Acknowledgments

The authors appreciate the excellent support of scientists and clinicians from the San Raffaele Scientific Institute of Milan, Italy, and the Stuttgart Cancer Center, Stuttgart, Germany.

Authorship

Contribution: A.J.M.F. and G.I. conceived the review, performed literature research, collected information, performed data analysis and interpretation, wrote the manuscript, and approved the final version before submission.
