ABSTRACTS OF SPECIAL INTEREST

A white man aged 71 was hospitalized with the clinical picture commonly associated with Waldenström's macroglobulinemia. The characteristic "lymphoreticular" hyperplasia, an increased number of tissue mast cells, and hypoplasia of the myeloid tissue were observed in sternal and iliac bone-marrow. Postmortem examination confirmed the diagnosis. Lymphatic leukemia, lymphosarcoma and multiple myeloma were not found. Chromosome studies were performed on sternal marrow cells by an original method which does not involve culture. The chromosome counts on 100 cells were:

The chromosome number ranged from 45 to 49, with a modal number of 47. Cells with 46 chromosomes had a normal karyotype, and were probably normal erythroblasts in mitosis. In all but five of the cells with 47 chromosomes, we observed an extra chromosome, morphologically well defined, which could be considered as a "marker" element. It was of the same size as the largest pair in the set, and the centromere was almost subterminal. Only in one cell with 48 chromosomes, and in one with 49 was this chromosome not seen; and it was present in many cells in which a count could not be confidently made.—M. J.

Previous studies of mitotic indices indicated a production of 16 x 10⁶ lymphocytes/hour in rats, and in man the number of lymphocytes entering via the thoracic duct equals the total number in the circulation. H³-thymidine studies in rats with thoracic duct fistulae were compatible with the hypothesis of lymphocyte recirculation (blood-lymph-blood) mainly via liver lymph vessels. This fact, and the assumed "recirculation" of lymphocytes via bone marrow (lymphocytes-bone marrow cells-blood cells), suggests a "carrier cell" function for lymphocytes to the author, possibly in the form of a DNA-transfer to other cells. The finding of labeled fibroblasts and epidermis cells in the wounds of rats, who were traumatized four days after receiving H³-thymidine, when the
only available radioactivity presumably was in lymphocytes, is compatible with the hypothesis of a DNA-transfer. Even in transplanted skin, some labeled epidermis-cells were found, and in this case the label could hardly originate anywhere but in host-cells. (Abstracter's comment: The definite demonstration of DNA-transfer would have profound implications upon the concept of cytoplasmic genes and of the manner in which cells receive information.)—P. G. R.

POST-IRRADIATION CHANGES IN PERIPHERAL WHITE BLOOD CELLS OBSERVED WITH FLUORESCENT MICROSCOPY. R. Harding, A. Stein and J. Maura.
From Albany Medical College, Albany, N. Y.

Previous workers demonstrated a post-irradiation change in the fluorescence of rat peripheral leucocytes and marrow stained with acridine orange. Cytoplasm of mononuclear and polymorphonuclear leukocytes usually fluoresces green in nonirradiated animals, but a substantial percentage will fluoresce red 3–24 hours following sufficient irradiation. The authors obtained serial specimens on 15 patients with various malignancies before, during, and after therapeutic courses of radiation to different areas. “Total roentgen doses” are tabulated, but no attempt was made to determine the dose-volume, i.e., gram-rad. About one-half of the patients showed the marked change in fluorescence noted earlier. The maximum percent of mononuclears fluorescing red before irradiation was 4.2 in one patient; several patients showed increases to 15–25 per cent post-irradiation. Nitrogen mustard appeared to produce a similar effect. The change in fluorescence is felt to be related to increased net cellular RNA content, whether from damage to existent cells, or increase in the peripheral percentage of young cells.—J. L. B.

A cell-free system from reticulocytes allows the incorporation of amino acids into microsomes and the synthesis of hemoglobin. The kinetics of both phenomena have been established. The incorporation of amino acids into microsomes requires an energy source, is activated by guanosine triphosphate, but may occur in the absence of pH 5 enzyme. Reticulocyte pH 5 enzyme is required for the biosynthesis of hemoglobin; it cannot be replaced by transfer ribonucleic acid nor by liver pH 5 enzyme. This suggests an organ-specificity for the pH 5 enzyme. Incubation with subcellular fractions obtained partly from rabbit and partly from guinea-pig reticulocytes allows both hemoglobins to be synthesized in all cases. However, when rabbit microsomes are incubated with chicken pH 5 enzyme, only rabbit hemoglobin is synthesized. The information needed for the synthesis of hemoglobin is carried by a factor present both in microsomes and in pH 5 enzyme. If the two fractions are not obtained from the same species, they apparently both express themselves only if the species are closely related.—G. M.

LEUKOCYTES

A chromatographic study on DEAE cellulose from normal leucocytes and from leucocytes of chronic myeloblastic leukemia has indicated the presence of three peaks of LAP activity. In acute leukemia the first peak was missing. Two other peaks appeared after blood transfusion.—P. d. N.

In leucocytes from normal subjects and from patients with acute and chronic myeloblastic leukemia, five peaks of LDH activity were identified by means of DEAE-cellulose columns. There is a reduction of the first peak in connection with the degree of immaturity of the leukemic cells, and an increase of peaks 2, 3, 4 in leukemic cells. —P. d. N.

Phosphorylase activity in leukocytes was found to be low in two cases of glycogen storage disease of the hepatic phosphorylase-deficient type. There was a good correlation between the relative amounts of the enzyme in the liver and the leukocytes of these patients. Study of peripheral blood leukocytes may provide a useful diagnostic approach in the glycogen storage diseases.—T. E. B.

CARBOHYDRATE METABOLISM IN LEUKOCYTES. IV. 

Rabbit polymorphonuclear leukocytes were incubated with glucose and galactose labeled in varying positions with carbon 14. The C\(^{14}\) distribution pattern in glycogen, lactic acid and lipid glycerol was then observed. The data from the glycogen degradations suggested that a small amount of the label reached glycogen by means of a transaldolase exchange reaction rather than through more direct pathways. Data from the lactate degradations suggested that the labeled hexoses were catabolized mainly by the Embden-Meyerhof pathway. Less than 0.1 per cent of the initial radioactivity of the labeled glucose was found to have entered lipids.—T. E. B.

The stimulation of leukocytic respiration which is known to occur when the leukocytes are incubated in the presence of latex particles was shown to vary markedly with both particle size and particle concentration.—T. E. B.

Guinea pigs were immunized with antisyphilitic vaccine. Samples of peritoneal exudates containing leukocytes were collected daily, and phagocytic activity assayed by incubation with Flexner's bacilli at 37 C. Every 10 minutes leukocytes from the incubation mixture were examined for phagocytic number (PN), glycogen, and peroxidase. In all situations maximum PN was obtained following 20 minutes incubation, after which the number declined. Highest PN of 1.89 (control = 0.82) was evident three days after the last injection of vaccine. The percentage of leukocytes showing peroxidase and glycogen was also highest on the same day. Since phagocytosis in nonimmunized animals uses up much peroxidase and glycogen, some evidence is here presented of the possible mechanism by which immunization increases the phagocytic power of cells.—J. J. B.

A single dose of P\(^{32}\) was given intravenously to rabbits and then serial studies were made of the specific activity found in various fractions of circulating leukocytes and of marrow cells. Rapid increase of labeled DNA-phosphorus in circulating leukocytes did not begin until about two days after injection, and maximum specific activity was reached four days after injection. Lymphocytes contributed little or not at all to the specific activity of circulating leukocytes. In marrow cells maximal labeled DNA-phosphorus was found within 24 hours of injection of P\(^{32}\).—T. E. B.

Fixed peripheral blood films were flooded with fresh normal urine before application of a Giemsa stain to the films. It was observed that in blood smears from patients with chronic myelocytic leukemia, nuclear blanching occurred, i.e. the nuclei of many neutrophil cells of all ages failed to take the Giemsa stain. Such nuclear blanching occurred only slightly in leukemoid reactions and did not occur at all in many other conditions including normals, patients with acute myelocytic leukemia, and patients with myeloid metaplasia. —T. E. B.

The intradermal inoculation (but apparently not the subcutaneous inoculation) of peripheral leukocytes before full thickness skin grafting resulted in accelerated rejection, sometimes markedly so, of the first set skin homografts. Skin homografts were provided simultaneously by both the leukocyte donor and a second nonspecific donor. Data obtained suggested that degree of acceleration of skin graft rejection seen was related to both the dose of immunizing leukocytes administered and the genetic similarity between the donor of the immunizing leukocytes and the donor of the nonspecific skin graft.—T. E. B.

It has been shown that lymph node cells taken from a rabbit recently immunized to a specific antigen and transferred to an homologous rabbit not immunized to the specific antigen will form antibodies in the recipient to the antigen in question. The capacity of the transferred lymph node cells to make antibody can be suppressed by prior injection of the recipient animal with an adequate number of donor peripheral blood leukocytes or by simply injecting the recipient animal with antiserum against rabbit leukocytes. Using this interesting system, the authors compared the immunologic responsiveness of neonatal and of mature rabbits. Several apparent similarities were found, but also one striking difference. The sera of neonatal rabbits injected with rabbit leukocytes were far less effective than similar sera from adult rabbits in passively transferring the suppressive effect on transferred lymph node cells.
—T. E. B.

The author discusses in the light of observations with the electron microscope the means by which antigens are absorbed into cells, the ultrastructure of plasma cells and lymphocytes, the means by which antibodies may be excreted from the cells in which they are formed, and, finally, morphologic changes found in malignant lymphocytes and plasma cells.—T. E. B.

The function of lymphocytes in the immunologic reaction has been studied. Lymphocytes were obtained from thoracic duct lymph. Passive transfer of immunity and hypersensitivity were attempted with lymphocytes or other types of cells. From these experiments, it was demonstrated that the lymphocytes participate directly in the production of both circulating and cellular antibodies. Rabbits tolerant of certain antigens either naturally or induced were altered in their immunologic response and became fairly reactive to these antigens with antibody production after receiving living homologous normal lymphocytes or lymph node cells. From these experiments the author suggests that immunologic tolerance might be a condition in which the lymphocyte failed in its function of antibody formation. The author showed that fractions of destroyed lymph node cells and lymphocytes had the ability to enhance antibody production in vivo when they are administered together with antigens, and that this reaction was enhanced by immunization. This function of lymphocytes was presumed to be due to the cooperation of microsome and soluble protein fractions.—K. F.

The authors studied cells proliferating in lymphoid tissue during immune graft reactions of host versus graft and graft versus host. Cells growing under these conditions usually show: a) An intense cytoplasmic basophilia as well as a large number of ribosomes, an increase in the Golgi body, and marked lipid vacuolization; several characteristics seen at ordinary microscopy differentiate them from plasmocytes, especially the absence of endoplasmic reticulum (absence of ergastoplasm) demonstrated by the electron microscope. b) Some of them, though more basophilic, look like hemocytoblasts, lymphoblasts and plasmocytoid lymphocytes; the greater majority look like Bessis’ histiocyte (mobile cell, differing from the reticulum cell). The authors draw a parallel between the absence of ergastoplasm in these cells and the lack of effective circulating antibodies during the immune graft reactions.
—G. M.

The function of lymphocytes in the immunologic reaction has been studied. Lymphocytes were obtained from thoracic duct lymph. Passive transfer of immunity and hypersensitivity were attempted with lymphocytes or other types of cells. From these experiments, it was demonstrated that the lymphocytes participate directly in the production of both circulating and cellular antibodies. Rabbits tolerant of certain antigens either naturally or induced were altered in their immunologic response and became fairly reactive to these antigens with antibody production after receiving living homologous normal lymphocytes or lymph node cells. From these experiments the author suggests that immunologic tolerance might be a condition in which the lymphocyte failed in its function of antibody formation. The author showed that fractions of destroyed lymph node cells and lymphocytes had the ability to enhance antibody production in vivo when they are administered together with antigens, and that this reaction was enhanced by immunization. This function of lymphocytes was presumed to be due to the cooperation of microsome and soluble protein fractions.—K. F.

Eosinophilia was induced in the peritoneal cavity of guinea pigs by the passive transfer of antigen-antibody complexes. The author believes that he has provided direct evidence that eosinophilia is induced by immune complexes, and he speculates at length upon the significance of his observation.—T. E. B.

Stored human marrow was incubated with tritiated thymidine and then marrow smears were studied by radioautography. The percentage of cells with specifically labeled nuclei was considered to be a useful index of marrow viability. After three days or more of refrigerator storage of a marrow specimen there was virtually no labeling to be a useful index of marrow viability. After

Normal whole blood being routinely stored in acid-citrate-dextrose solution was found to develop marked resistance to passage through a microfilter with multiple openings 20 μm. This property appeared within 2–10 days of beginning blood storage and was shown to be produced principally by the formation of aggregates of platelets and leukocytes. Such aggregates can be efficiently removed by passage of the blood through glass wool but not by passage through the routine filter of a transfusion set. The author wonders if the platelet-leukocyte aggregates might not be capable of producing widespread micro-infarctions in the organs of the blood recipient.—T. E. B.

Eight different leukoagglutinating sera from multiparous women were used to study the inheritance of human leukocyte antigens. The data obtained were consistent with the hypothesis of genetic control of leukocyte antigens.—T. E. B.

This is apparently the first reported case of agranulocytosis associated with amphenidone therapy.—T. E. B.

Necropsies of 157 cases of acute leukemia indicated hemorrhage to be primary cause of death in 43 cases (20 in central nervous system and 15 generalized). In 55 cases, infection was the primary cause (pulmonary in 33 cases and generalized in 15); and in 19 cases acute ulcerations in gastrointestinal tract proved lethal.—P. G. R.

In an initial series of 40 cases of malignant lymphoma, 5 coexistent carcinomas were found, 4 of which were among 20 cases with lymphosarcoma. In later series of 100 "benign" rectal lymphomas there were 7 cancers. The present series contains 585 autopsies, 265 leukemias with 9 coexistent carcinomas, 43 myelomas with 2 carcinomas, and 280 malignant lymphomas with 6 cancers. These incidences do not indicate a correlation between cancer and leukemia.—P. G. R.

RADIATION INJURY

From the parent colony, (brother-sister mated for over 40 generations), two male-female pairs were selected, one to establish the “control” line, the other to begin the experimental line. The former pair was mated at maturity, and serial sib-mating at maturity was carried out to the F-12 generation, 58 of which served as the final control group. The “experimental” line was similarly carried, except that each male at 28 days of age received 200 rads of whole body radiation, from the F₁ through the F₁₀ generations inclusive. The F₁₁ male was not irradiated, and 85 mice from the succeeding (F₁₂) generation served as the final “experimental” group. At 42 days of age, experimental and control groups were both placed in Co₆₀ exposure fields of 4.17 rads/hour and maintained until death. Mean accumulated doses for males and females of the irradiated line were respectively 23 per cent and 26 per cent less than for the control groups, at the 0.01 level of significance. An accumulation of recessive and/or sublethal mutants in the ten generations of irradiated males is proposed.—J. L. B.

**ABSTRACTS**

**Structural, Cytologic and Autoradiographic (H³-Thymidine) Changes in the Bone Marrow Following Total Body Irradiation. T. M. Fleitner, V. P. Bond and E. B. Cronkite. From the Medical Research Center, Brookhaven National Laboratory, Upton, L. I., N. Y. Am. J. Path. 38:5, 1961.**

Rats received 550, 1000, and 1500 r and were sacrificed one hour or 10 days later. They received H³-thymidine one-half hour before death.

The authors followed the induction and development of osteosarcomas with serial roentgenograms, following the intravenous administration of Sr₉₀ in equilibriu with γ⁹⁰ in a dosage of 0.9 μc/Gm. (average) to 29 CF-1 and 1.03 μc/Gm. (average) to 24 CBA mice. The animals were females of 10 weeks approximate age. One hundred and twenty-five osteosarcomas developed in the CF-1 mice, the first at 98 days and 50 per cent by 175 days with a Poisson distribution. Ninety-six osteosarcomas appeared in the CBA mice, the first at 180 days, and 50 per cent by 245 days with a similar distribution of incidence. Considerable variation was noted in 1) the number of

The author differentiates pathologic processes which occur more frequently with increasing age from the more subtle reductions in organ function and cell population that may more accurately manifest the aging process. A breakdown is presented of the major tissues and organs of man, with respect to parenchymal radiosensitivity and the morphologic and functional decline with aging. Some parallelism is noted, but the picture is clouded because of 1) the dependence of tissues on an intact vasculature and 2) paucity of data on functional and reserve capacities of tissues and organs. The conclusion is that radiation may become a valuable tool toward clarification of the aging process, but not until physiologic assay can be improved.—J. L. B.

**Life-Shortening in Mice Irradiated with Either Fission Neutrons or Cobalt-60 Gamma Rays. H. H. Vogel, Jr. et al. From the Argonne National Laboratory, Argonne, Ill. Radiology 77:600-613, 1961.**

The authors studied life-shortening in mice exposed to 13 daily doses of either 1) fission neutrons at 4.4 rads per minute or 2) Cobalt-60 γ-rays at 13 rads per minute. Graded exposures in each case were achieved by stepping the length of each daily exposure. Fifty per cent reduction in mean life span was effected by either 480 rads of Co₆₀ gamma or 300 rads of fission neutrons with a resultant relative biological effectiveness (RBE) for the neutrons of 1.6. Repetition of this experiment, with reduction of the dose rate for both radiations to one rad per minute, resulted in values of 888 (plus) rads for Co₆₀ gamma and 350 rads of neutrons, with an RBE for neutrons of 2.5 (plus). A third experiment demonstrated no significant difference in life shortening by fission neutrons, whether delivered in one brief exposure or in a series of 10 daily fractions. The authors conclude that similar RBE values of fission neutrons were obtained for life-shortening as for their previous 30-day 50 per cent lethality study, and discuss the findings with other data in the literature.—J. L. B.
tumors per animal and 2) the relative rates of growth of different tumors in the same animal. Mortality curves for the two strains lagged behind the respective tumor incidence curves by about 30 days. Analysis of the roentgenogram data revealed no predilection of tumor for any particular bone. Plotting of absolute tumor incidence (by radiographic evidence) versus time post-treatment revealed a leveling off of morbidity at a rate of 8-10 new tumors/100 mouse days, for both strains. Plots of calculated tumor volume, as a function of time, are discussed, with some difference in rate of tumor growth noted, depending on the anatomical site. The authors point out the difference in tumor morbidity determined by roentgenogram as compared to the frequently employed collection of morbidity data at demise. Concluding discussion relates to the apparent three phases of osteosarcoma growth, with what appears to be prolongation of the first phase in the CBA mice. (Abstractor's note: It would be of interest to determine whether the maximum morbidity rate is a function of initial Sr90 dose).—J. L. B.

UNUSUAL BONE TUMORS AFTER ROENTGEN THERAPY OF CHILDREN. J. Cohen and G. J. D'Angelo.

The authors review 8,321 cases of children treated with ionizing radiation from 1938 to 1957 inclusive. Of these, 7,423 with benign processes received estimated bone doses of generally less than 500 r and rarely over 1,000 r, and showed no incidence of postirradiation bone tumor. Eight hundred and ninety-eight cases, generally less than 500 r and rarely over 1,000 r, and showed no incidence of postirradiation bone tumor. Whole body and partial body (various areas) exposure to 1000 r demonstrated that irradiation of 10 cm. of jejunum produced as much PVP excretion as entire intestine irradiation, and more than whole-body irradiation. Animals with biliary fistulae did not experience an increase in fecal PVP postirradiation, even when the collected bile was reinjected. This mechanism was not clear. Cysteine (pre-irradiation) significantly reduced PVP excretion. —J. L. B.

In vitro preparations of dog and swine aorta were made whereby perfusion with Tyrode's solution and simultaneous irradiation with a Co60 source could be accomplished. With an exposure rate of 626 r/min., 20–52 per cent of arteries tested (in replicate experiments) constricted slightly during the first minute of radiation, and dilated to normal size during the first minute following completion of the usual 15 minute irradiation period. This effect was also seen when mineral oil replaced the Tyrode's solution surrounding the artery. Decreases in vasa vasarum flow obtained under the first conditions, however, were not

This paper describes 80-day survival and daily food consumption in four major categories: 1) non-irradiated, 23 C. environment; 2) nonirradiated, 6 C. environment; 3) irradiated, 23 C. environment; and 4) irradiated, 6 C. environment. All irradiations were 250 KVP x-rays at 25 r/min., 40 inch TSD, and HVL = 1.5 m\(\mu\)c, to the same total dose of 600 r, but multiple groups of 14–25 rats each at both temperatures were provided to allow either single exposures or 8-part fractionation, the latter with intervals of 1, 3, 5, or 7 days. Survivals resulting from the single exposure were 35 per cent at 23 C., but only 5 per cent at 6 C. Significant increase in survival with fractionation appeared with irradiation intervals of 24 hours for the 23 C. animals, but not until intervals were increased to 48 hours for the 6 C. animals. Food consumption in irradiated groups at both temperatures fell below their respective controls, but rose to control levels by the 10–15th day postirradiation in the 24-hour interval rats. “Pair-fed” nonirradiated rats at both temperatures (restricted in feeding each day to the same quantity consumed the preceding day by the respective irradiated [75 r daily group] underwent initial weight loss and subsequent recovery comparable to the irradiated animals at both temperatures. Twenty-five per cent mortality appeared in the pair-fed nonirradiated rats maintained at 6 C. Possible mechanisms are not discussed.—J. L. B.

Strength, upright and righting reflexes, and locomotor learning were tested at one month of age in 500 rats derived from mothers receiving 25, 50, or 100 r on day 5, 10, 15, or 20 of the 22-day gravid period. Radiation was 250 KVP, HVL = 1.8 m\(\mu\)c, at an “in air” dose rate of 9.4 r/min. Results showed reduction to 57 per cent of normal in both upright and righting responses (significance at the 0.05 level) for offspring receiving 100 r on the 15th intrauterine day. The same group performed at only 13 per cent of normal (significance at the 0.01 level) in strength testing, and showed reduction in locomotor learning (significance at the 0.01 level). Findings are briefly discussed with respect to fetal maturation.—J. L. B.

This editorial presents a brief but lucid historical review beginning with the early concept that thymic hypoplasia progressing to status thymic lymphatic with possible “sudden death,” was adequate justification for the use of ionizing radiation to induce thymic atrophy. Despite several opponents in the 1920’s, diagnosis and treatment of enlarged thymus glands became increasingly popular until the late 1930’s, after which the significance of status thymic lymphaticus began to be questioned. Following the use of atomic bombs over Hiroshima and Nagasaki, and direction of public attention to biological effects of radiation, rationale for thymic irradiation further decreased. Many articles have appeared both for and against an increased incidence of thyroidal cancer in persons previously receiving irradiation of their thymus glands. The author points out that, whether pro or con, most workers have ceased thymic irradiation for benign conditions. Extreme thymic enlargement with appreciable impingement upon the trachea is however felt to justify small doses of radiation to small portals directly over the thymus.—J. L. B.

Major types of accidents are noted, whereby individuals may be exposed to radiation from outside sources or internal contamination. An outline in detail is presented with major headings as follows: I) Patient Evaluation at Accident Site, II) Admission Room Management of Radiation Disaster Victims, III) Prognosis for Patients Exposed to External Radiation (where dose may be estimated), IV) Types of Exposures (with delineation of body areas of probable maximum radiation effect, according to type of exposure), V) “General” Exposures (outlining of supportive measures according to degree of exposure for various periods postirradiation), VI) Antibiotics (with emphasis on cultures, but restriction of
ABSTRACTS

antibiotics to actual cases of infection), VII) "Superficial" Radiation Exposure, and VIII) The Induced Radiation Case (activation of the patient, as in reactor "excursions"), and IX) Internal Contamination. Discussion follows each outline.—J. L. B.

HEMOSTASIS

Antifibrinogen sera were obtained by immunizing rabbits with human fibrinogen. Specificity was tested by means of double diffusion agar-gel and microimmunoelectrophoretic technics, and by incubation of plasma or fibrinogen with antifibrinogen serum. The antifibrinogen antibodies were also detected in rabbits born from immunized mothers.—P. d. N.

Seventy-five patients received daily intramuscular injections of 100 µg of vitamin B12 for 14 days. In most of them, plasma cholesterol fell by 20 per cent irrespective of the original level, whereas plasma phospholipids increased. As a result the phospholipid/cholesterol ratio rose to above one. Little change was observed in prothrombin levels, but in a few instances the prothrombin time was shortened.—J. J. B.

Studies on blood coagulation in atherosclerosis were carried out with the purpose of establishing 1) the interrelationships between the alterations of blood coagulation due to the atherosclerotic process and those due to advanced age; 2) the influence of cholesterol on blood coagulation in experimental hypercholesterolemia; and 3) the modifications of blood coagulation due to atherosclerosis following the treatment with essential phospholipids. It has been shown that aging it-self may partly influence the onset of the hypercoagulable states, which are observed in elderly atherosclerotic subjects, and that other factors (e.g. increased blood pressure) may interfere with interpretation of these findings. Experimental hypercholesterolemia is not accompanied by a state of hyper- but of hypocoagulability, and it should thus not represent a decisive factor in the pathogenesis of thrombophilic states in atherosclerotics. The administration of essential phospholipids is able to reduce the hypercoagulability due to fatty meals, which is particularly marked in atherosclerotics, and also the thrombophilic state under basal conditions in the same patients.—P. d. N.

Among 303 cases of diabetes, thrombelastographic values were normal in 49, showed slight hypercoagulability in 7 per cent and definite signs of hypercoagulability in 44 per cent of cases. No correlation was found between thrombelastographic values and treatment, blood sugar, weight, blood pressure, retinal lesions, prothrombin activity, factor VII, tourniquet test, petchiometry, platelet count, and duration of the disease. A good correlation was found with recalcification time, heparin tolerance, urea clearance, fibrinogen.—P. d. N.

Among 303 diabetics, factor VII was normal in 11 per cent, moderately increased in 31 per cent and markedly increased in 58 per cent of the patients. No correlation was found between factor VII and age, duration of disease, weight, blood pressure, therapy, blood sugar, retinal lesions, tourniquet test, petchiometry, platelet count, recalcification time, thrombelastogram, heparin tolerance and urea clearance. Good correlation was found with sex, prothrombin time and fibrinogen.—P. d. N.

Sarcoma Type M-I or Type 45 was transplanted into male rats. In 20 controls, average plasma fibrinogen was 340 mg./100 ml. and thromboplastic activity 90 sec. During tumor growth a rise in fibrinogen and an increase in thromboplastic activity were observed. The change started almost immediately after transplantation. In two weeks, average level of fibrinogen was 920 mg./100 ml. and thromboplastic activity 59 sec. Little difference was observed between the two types of tumor.—J. J. B.

OWREN’S THROMBOTEST: A NEW METHOD FOR THE CONTROL OF INDIRECT ANTICOAGULANTS.

Thrombotest was used for controlling the anticoagulant activity of an indanedione derivative. A good correlation was found between thrombotest and the P & P method. A less satisfactory correlation was found with the prothrombin time. Thrombotest is particularly suitable for detecting factor IX modifications, particularly when prothrombin activity is less than 20 per cent. The simplicity of the technic and the consistent results obtained are outlined. The possibility of preventing hemorrhagic complications by means of thrombotest represents a considerable advantage for long-term anticoagulant therapy.—P. d. N.

ERYTHROCYTES

Normal rabbits and rabbits treated with multiple injections of colcemid were given an intravenous injection of 5 μc/Kg. of Fe followed by a second “flooding dose” of nonradioactive iron in order to determine the iron utilization of their erythrocytes. The maturation time of the most immature erythroblasts (proerythroblasts) and the mature erythroblasts (incapable of division) was calculated from the time necessary for the iron utilization of erythrocytes of both groups of animals to reach the maximum level. Reticulocyte maturation time was estimated in the injected animals by successive determinations of the reticulocyte counts after the injection of colcemid. 1) In normal rabbits the maturation time of the mature erythroblasts averaged 16.8 ± 2.4 hours, and the time required for the most immature erythroblasts (proerythroblasts) to grow into the circulating reticulocytes was estimated to be 73.5 ± 3.8 hours. 2) Reticulocyte maturation time averaged 28.5 ± 3.1 hours, which coincided with the calculated value based on the estimation of erythrocyte life span and the reticulocyte percentage, i.e., 25.9 ± 4.3 hours.—K. F.

Lactic dehydrogenase (LDH) and leucylamino-peptidase (LAP) were studied in erythrocytes by means of column chromatography on DEAE cellulose. LDH was similar in normal erythrocytes and in erythrocytes from patients with Cooley’s disease. LAP was different in the two conditions.—F. d. N.

HEMOPOietic Activity in Petroleum Poisoning.

Guinea pigs were poisoned by petroleum inhalation (60 mg. per liter, for 80 days, 8 hours daily, in a chamber of 10 M³, at 28 C.). Erythrocytes, leukocytes, platelets, reticulocytes, hemoglobin, erythrocyte diameter and volume, osmotic fragility of erythrocytes, differential count of leukocytes, Arnett count, platelet agglutinability and adhesiveness, hematocrit value, and bone marrow biopsies were carried out. Alterations were first detected in the peripheral blood, as a diminution of the various values, and later in the bone marrow, particularly in the erythropoietic and thrombocytopoietic series, both in the formation and evolution of the concerned elements.—P. d. N.
