Unified Hypothesis for the Origin of Aplastic Anemia and Periodic Hematopoiesis

By Michael C. Mackey

The clinical and laboratory data related to periodic hematopoiesis (PH) are briefly reviewed, and it is concluded that the dynamics of PH probably originate in the hematopoietic pluripotential stem cell (PPSC) population. A model for the PPSC population is developed and analyzed. Based on the model, the simplest hypothesis for the origin of aplastic anemia (AA) and PH is that they are both due to the irreversible loss of proliferative stem cells. In addition to offering estimates for normal PPSC parameters in man and dogs, the model offers an explanation for the rarity of PH and its observed dynamics. The hypothesis predicts that for subjects without proliferative PPSC loss and with a normal differentiation flux $M^*$ out of the PPSC, the effect of cell loss from proliferation will be hypocellularity and pancytopenia. However, in both man and dogs with an $M^*$ significantly less than normal, loss of proliferating PPSC at a low rate gives mild pancytopenia, loss at a higher rate gives PH, and at an even higher rate severe pancytopenia appears. The threshold $M^*$ for the appearance of PH in man is predicted to be about $3.7 \times 10^7$ cells/kg/day at a minimal period of 17 days. For mongrel dogs, the $M^*$ at which PH ensues is $6.6 \times 10^7$ cells/kg/day and the period is about 9 days. Finally, the hypothesis predicts that the PPSC in subjects with AA and PH will have an increased proliferative fraction, and that stem cells should display an increased doubling time during periods of exponential growth.

Cyclic Neutropenia (CN) is a disease characterized by an oscillation in circulating neutrophil numbers from normal to low values. In man the majority of cases display a period in the range of 17 to 28 days. All grey collies have this disorder, apparently differing from human CN only in that the period is 11-12 days. In CN in both man and the grey collie a concomitant oscillation of all of the formed elements of the blood is observed. These elements oscillate with the same period as the neutrophils, but with phase lags or leads consistent with the known differences in maturation times for each of the cell types. Thus this disorder is more appropriately termed periodic hematopoiesis (PH) or cyclic hematopoiesis (CH).

The granulocyte turnover rate (GTR) in grey collies ranges from normal to low values, and the neutrophil half-life is normal. A similar observation has been made in humans with CN, implying the existence of a marrow production defect. In line with this possibility, it has been noted that in the collie normal hematopoiesis results when normal bone marrow is transplanted into an irradiated grey collie. Conversely, the transplantation of marrow from grey collies with PH into irradiated normal collies is marked by the onset of PH in

Both of these results have been confirmed, and they demonstrate that a component of the marrow, probably the pluripotential stem cell (PPSC), is the primary location of the defect responsible for the peculiar dynamics of periodic hematopoiesis.

Cyclic neutropenia has received some attention from theoreticians who have examined the potential involvement of a long-range (circulating to stem cell) humoral control mechanism in the genesis of the disorder. It is known that colony-stimulating factor (CSF) and serum erythropoietin (ESF) levels in grey collies and humans with CN oscillate with a period identical to the circulating cellular period. However, it is also known that CSF and ESF are not regulators of the PPSC population. Thus a significant involvement of peripheral to stem cell humoral feedback mechanisms in periodic hematopoiesis is unlikely.

The available clinical and laboratory data seem most consistent with the view that periodic hematopoiesis is due to a short-range defect at the pluripotential stem cell level, manifested by a periodic failure of the production of all formed elements of the blood.

Aplastic anemia (AA), by definition, is characterized by a mild to severe pancytopenia and hypocellular bone marrow. It is frequently observed as a result of chemotherapy and radiotherapy. It has been argued that the primary locus of the defect in aplastic anemia is resident in the PPSC population, and that the defect may be either transient or permanent.

In this paper the analysis of a model for the control of stem cell production is presented. Based on the analysis, it is demonstrated that a sufficient explanation for the origin of aplastic anemia and periodic hematopoiesis is the existence of irreversible cell loss from the proliferating phase of the cell cycle.

THE MODEL

A schematic representation of the pluripotential stem cell model is shown in Fig. 1. The equations describing the model, with heuristic arguments for their structure, and a list of symbols used are given in Appendix 1.

Stem cells are classified as proliferating-phase (population \( P \), cells/kg) or resting-phase (\( G_0 \)) cells (population \( N \), cells/kg). The distinction between the proliferating and resting states is as follows: Cells travel through proliferation as if in a pipeline to undergo mitosis at a fixed time \( \tau(d) \) from their time of entry into the proliferative state. However, cells entering \( G_0 \) may exit randomly due to pathologic loss of cells from proliferation. See text for further details.
to either reenter proliferation at a rate $\beta(d^{-1})$ or to be irreversibly lost via differentiation into the hematopoietic lines at a rate $\delta(d^{-1})$. Although proliferating cells in the model may be irreversibly lost at a rate $\gamma(d^{-1})$ from any phase of the cell cycle, here a “normal” stem cell population will, by definition, be characterized by $\gamma = 0$. Assume throughout that $\gamma$, $\delta$, and $\tau$ are constant with respect to time and cell population numbers.

Control mechanisms within stem cell populations are not well understood, although there exists strong evidence for potent short-range mechanisms (as opposed to long-range circulating regulators) acting to limit stem cell numbers.\textsuperscript{17,25–28} Without specifying the exact nature of control, assume that the PPSC population is capable of recognizing the number of $G_0$ phase cells and changing the mitotic reentry rate $\beta$ in response to changes in $N$ (see Appendix 1). Specifically, when the $G_0$ population is small $\beta$ approaches a maximum, and when $N$ increases $\beta$ decreases as shown in Fig. 2. In Fig. 2 the parameter $\beta_0(d^{-1})$ is the maximal rate of cellular entry into proliferation, and $\theta$ (cells/kg) is the number of $G_0$ cells at which $\beta$ has its maximum rate of change with respect to $N$.

The maximum slope of the $\beta$ versus $N$ relationship, which occurs at $N = \theta$, is $-n\beta_0/\theta$, where $n$ is a dimensionless number.

As outlined in Appendix 2, the stem cell model of Fig. 1 has steady-state proliferating and resting cellular populations $P^*$ and $N^*$ (cells/kg). The time-dependent behavior of the populations $P(t)$ and $N(t)$ falls into one of two broad classes that are of importance for understanding aplastic anemia and periodic hematopoiesis. Thus from numerical and analytical studies (see Appendix 2) the PPSC populations will either (1) approach the steady-state populations $P^*$ and $N^*$ [given by Eqs. (2.1)\textsuperscript{†}] in a smooth or damped oscillatory fashion, or (2) oscillate in a stable fashion around the steady-state population values $P^*$ and $N^*$. The oscillation may be either periodic or aperiodic, depending on the choice of parameters.

Although the parameter $\theta$ is involved in determining the magnitude of the steady-state populations, it plays no role in determining which of these two behaviors the stem cell population will exhibit. That behavior is completely determined by the values of the kinetic parameters $\gamma$, $\delta$, $\beta_0$, $\tau$, and $n$. Generally speaking, if all five of these parameters are such that the populations approach a steady state, then an increase in any one of the parameters with the other four

\textsuperscript{†}Equation (2.1), for example, is to be found in Appendix 2.
held constant may lead to the appearance of oscillations. Even in the case where $\gamma = 0$, increases in $\delta, \beta_0, \tau$, and/or $n$ may lead to a transition between these two behaviors.

The notion that control systems with a time delay may become unstable and start to oscillate is one familiar to control engineers. A simple example of this phenomenon is available in the mundane workings of a home heating unit. If the delay is too long between times when changes in temperature are made and when they are sensed, the temperature may start to oscillate around the set point (roughly analogous to $\theta$). Likewise, if the thermostat is too sensitive ($\beta_0$ or $n$ too large), the temperature may begin to overshoot and undershoot the desired value. Finally, if heat loss from the house (loosely analogous to $\delta$) or from the furnace ($\gamma$) is too great, oscillatory excursions about the desired temperature may ensue.

The determination of values for the set of parameters $\gamma, \delta, \tau, \beta_0, n$, and $\theta$ is difficult because of their number and the lack of any large body of data related to stem cell physiology and pathophysiology. A detailed treatment of the parameter determination is given in Appendix 3.

Normally, $\gamma = 0$, although a number of agents may cause the death of proliferating-phase stem cells. To determine $\delta$ and $\tau$, assume that (1) the proliferating fraction $F_p$ of the stem cell population is at most 0.10 and (2) the total stem cell population is $5 \times 10^{10}$ cells/70 kg. These two assumptions allow unique values of $\delta$ and $\tau$ to be calculated for any value of the steady-state flux of cells, $M^* = \delta N^*$ (cells/kg/day), into the differentiated hematopoietic lines (myeloid, erythroid, and thrombocytic). Using these values for $\delta$ and $\tau$, and further assuming that (3) the doubling time $t_d$ for the stem cell population is 24 hr when the population undergoes exponential growth, allows a unique value for $\beta_0$ to be calculated. The variation in $\delta, \tau$, and $\beta_0$ with $M^*$ is shown in Fig. 3 for a range of differentiation fluxes.

There are few data on which to base a choice for $n$, which controls the sensitivity of the mitotic reentry rate (Fig. 2) to changes in the size of the $G_0$ phase. If the interpretation offered in Appendix 1 for the form of $\beta$ is correct, it would be expected that $n$ would be small (on the order of 5 or less). The response to one mitotic regulator, granulocytic chalone derived from rat granulocytes, is described by the form for $\beta$ adopted here [Eq. (1.3)], with $n = 3.15$ (coefficient of concordance $r^2 = 0.99$), lending further support to the notion that $n$ is not

![Fig. 3. PPSC parameter values. Variation $\delta$ in the rate of cellular differentiation out of $G_0$, cell cycle time $\tau$, and maximal rate $\beta_0$ of $G_0$ cell movement into proliferation as a function of flux $M^*$ of cells into differentiated hematopoietic cell lines. $\delta$ directly proportional to $M^*$; $\tau$ is inversely proportional to $M^*$. $\beta_0$ determined as a function of $\delta$ and $\tau$. See text and Appendix 3 for details.](image-url)
large. In point of fact, \( n \) is determined in this study by the peculiar dynamics of periodic hematopoiesis in man and dogs.

Once a value is assumed for \( n \), the final parameter \( \theta \) may be calculated with the previously determined values of \( \beta_0 \) and \( \delta \) in conjunction with the estimate for \( N^* \) and Eqs. (2.1).

**ORIGIN OF APLASTIC ANEMIA AND PERIODIC HEMATOPOIESIS**

In examining this pluripotential stem cell model with respect to the origins of aplastic anemia and periodic hematopoiesis, I conclude that they may both have a common origin. More specifically, they may both be encountered as a single dynamic parameter within the stem cell population is changed.

Evidence has been recently reviewed\(^{22}\) that tends to support the hypothesis that the PPSC in aplastic anemia is abnormal with respect to proliferative function. This concept is supported by the observation that the administration of a single large dose of busulfan in mice results in a permanent transformation in the proliferative capacity of marrow stem cells, manifested by mild to severe marrow hypoplasia and pancytopenia.\(^{34}\)

Insight into the origin of periodic hematopoiesis is afforded by examining the effects of continuous cyclophosphamide and busulfan administration in normal dogs.\(^{35,36}\) Usually there is a simple progressive pancytopenia that becomes more severe with higher drug doses. However, in some animals this pattern is altered to one in which low drug levels give simple pancytopenia, higher levels result in cyclic neutropenia (with a period of 11-17 days), and even higher dosages abolish the cyclic neutropenia, leaving the dogs severely pancytopenic. The onset of cyclic neutropenia, when it occurs, is at a circulating neutrophil level of one-half to one-third normal. Furthermore, the appearance of cycling granulocyte levels in a number of patients undergoing continuous hydroxyurea therapy,\(^{17}\) and in one patient receiving cyclophosphamide,\(^{38}\) has been noted.

Cyclophosphamide and busulfan are alkylating agents, while hydroxyurea is an antimetabolite.\(^{29}\) Hydroxyurea is known to selectively kill proliferating pluripotential stem cells during DNA synthesis.\(^{27,39}\) Likewise, cyclophosphamide kills stem cells,\(^{25}\) and within the context of this study I interpret the mode of action of all these agents to be one resulting in \( \gamma = 0 \). If \( \gamma \) is not zero in the stem cell population, then it can be shown that the total steady-state PPSC population \( P^* + N^* \) continuously decreases in size as the rate of irreversible cell loss from proliferation increases. The steady state flux of cells, \( M^* = \delta N^* \) (cells/kg/day), out of \( G_0 \) into all of the hematopoietic lines will also decrease, resulting in pancytopenia.

Figure 4 deals with the implication of killing proliferating-phase stem cells in a previously normal PPSC population; therein is plotted the predicted steady-state cellular flux into the differentiated hematopoietic lines, \( M^* \), as a function of the rate of irreversible cell loss from proliferation. I have assumed \( n = 3 \) and selected parameters corresponding to a normal differentiation flux for man of \( 1.05 \times 10^6 \) cells/kg/day when \( \gamma = 0 \). As may be seen in this example, the total PPSC population numbers decrease with increasing \( \gamma \), as does the total flux into the differentiated hematopoietic lines. Also, with increasing
\( \gamma \) the proliferating fraction \( F_p \) continuously increases, as does the doubling time \( t_D \) during exponential growth. Thus increasing the rate at which the PPSC loses cells from proliferation results in a generalized pancytopenia and, presumably, a marrow hypocellularity.

Figure 5 indicates that for an initial (\( \gamma = 0 \)) \( M^* \) less than the mean for man, the lower the initial \( M^* \), the more profound will be the pancytopenia developed as \( \gamma \) increases. For an initial \( M^* \) less than \( 3.86 \times 10^7 \) cells/kg/day, an abrupt change in the behavior of the stem cell population becomes apparent as \( \gamma \) is increased. Thus for an initial \( M^* \) of \( 3.81 \times 10^7 \) cells/kg/day a progressive increase of \( \gamma \) leads to a progressive decrease in \( M^* \). Based on the analysis of
Appendix 2, it is predicted that when $\gamma = 0.30/\text{day}$ $M^*$ will no longer be depressed and constant but will start to oscillate with a period of 16.5 days, the onset of periodic hematopoiesis. Progressive increases in $\gamma$ beyond this value lead to a progressive increase and then decrease in the amplitude of this oscillation, accompanied by an increase in the period, until at about $\gamma = 0.33/\text{day}$ (with a period of 19 days) the periodic hematopoiesis ceases and a steady pancytopenia reappears.

Figure 6 shows a sequence of computed PPSC population numbers as a function of time, assuming an initial $M^*$ of 3.22 $\times$ 10^7 cells/kg/day and all other parameters corresponding to this $M^*$ as given in Fig. 3. The solutions shown in Fig. 6 start from the normal steady-state values for $N^*$ and $P^*$ and show the expected changes over a 100-day interval if, at $t = 0$, $\gamma$ is suddenly changed from $\gamma = 0$ to the value indicated in each panel. The sequence of events is as follows: (1) For values of $\gamma < 0.24/\text{day}$ there is a simple depression in $P^*$ and $N^*$ below their normal steady-state values and thus a decrease in $M^*$; (2) For values of $\gamma$ in the range in which periodic hematopoiesis is predicted (see Fig. 5; 0.24 $\leq$ $\gamma$ $\leq$ 0.29/\text{day}) the $G_0$ cellular population numbers oscillate, initially with a period of approximately 19 days, which lengthens to 25 days for $\gamma$ near 0.29/\text{day}; (3) For $\gamma > 0.29/\text{day}$ the $G_0$ population numbers are even more depressed but constant.

The stem cell population dynamics displayed in Figures 4 through 6 adequately duplicate the qualitative and quantitative properties of aplastic anemia and periodic hematopoiesis in humans.

The same qualitative sequence of behaviors shown in Figs. 4-6 is found for higher values of the parameter $n$. The quantitative differences in this pattern as $n$ is increased are twofold: the larger the value of $n$, the larger the initial flux into differentiation at which the periodic hematopoiesis will initially be found, and the larger the value of $n$, the shorter the period of the oscillation. With these points in mind, it is clear that an explanation of the patterns of periodic
hematopoiesis in grey collies, and the results of continuous administration of cyclophosphamide and busulfan, will require a value of $n$ greater than for man.

These points are illustrated in Fig. 7 for $n = 4$. As indicated, the transition from simple pancytopenia to periodic hematopoiesis requires an initial $M^*$ of $6.56 \times 10^7$ cells/kg/day. The period of the periodic hematopoiesis, when it occurs, is about 9 days. Progressive decreases in the initial $M^*$ lead to progressive increases in the period of the oscillation.

Fig. 8 shows, for $n = 4$ and an initial $M^* = 5.19 \times 10^7$ cells/kg/day, the sequence of behaviors encountered as $\gamma$ is increased. The analysis of Appendix 2...
PERIODIC HEMATOPOIESIS

indicates that mild aplastic anemia should result for all values of \( \gamma < 0.31/\text{day} \), that periodic hematopoiesis (with an initial period of 10.4 days) will be present for \( 0.31 \leq \gamma \leq 0.44/\text{day} \), and that severe hypocellularity and pancytopenia will appear for \( \gamma > 0.44/\text{day} \).

**DISCUSSION AND PREDICTIONS**

Since the populations of the stem cell model are capable of sustained oscillations when \( \gamma = 0 \), the most parsimonious assumption would be that aplastic anemia and periodic hematopoiesis are due to the alteration of one of the parameters \( \theta, \theta_0, \delta, n, \) or \( \tau \). An analysis of the effects of changes in these parameters on the flux of cells out of \( G_0 \) reveals that it is only by an increase in \( n \) that pancytopenia and marrow hypoplasia followed by the appearance of periodic hematopoiesis, as observed in cyclophosphamide-treated dogs,\(^{35,36} \) can be effected. It is common in aplastic anemia to find a pancytopenia of 50\(^\circ\)\(_o\) or more.\(^{21} \) A simple calculation indicates that within the estimated range of normal parameters \( n \) would have to be increased from a normal value of 3 to about 12 for man, or from a value of 4 to about 125 for dogs, in order to account for this reduction. This notion seems untenable on several grounds, not the least of which is that the analysis of Appendix 2 indicates that periodic hematopoiesis will occur long before any detectable pancytopenia occurs.

Thus in examining AA and PH, attention is sharply focused on the proliferative loss rate \( \gamma \) from the PPSC. The analysis in Appendix 2 of the PPSC population dynamics and the results of that analysis displayed in Figs. 38 indicate that increasing the proliferative loss rate will have one of two effects: (1) a decrease in the total PPSC population numbers, accompanied by a generalized and steady pancytopenia, or (2) a reduction in the PPSC and steady pancytopenia for low values of \( \gamma \), PH for higher values of \( \gamma \), and severe but steady pancytopenia for even larger \( \gamma \). Therefore the prolonged marrow hypocellularity and pancytopenia associated with idiopathic AA, or AA due to chemotherapy or radiotherapy, is adequately accounted for by this model for the PPSC. Likewise, the dynamics of idiopathic PH and the pattern of induction of PH with cytotoxic drugs are encompassed by a unified explanation.

Thus a sufficient explanation for the origin of aplastic anemia and periodic hematopoiesis is that they are both due to irreversible cellular loss from the proliferating pluripotential stem cell compartment.

In addition to offering estimates for the parameters characterizing the production and control of pluripotential stem cells, this hypothesis offers a satisfying explanation for two observations: (1) Spontaneous periodic hematopoiesis in man and dogs is rarely observed. This finding is a consequence of the fact that in the model PH is encountered only in subjects who initially (\( \gamma = 0 \)) have an \( M^* \) far below the average value. (2) Spontaneous periodic hematopoiesis in man and dogs, when it occurs, displays a periodicity equal to or greater than about 17 and 9 days, respectively. In the model, this observation serves to place some constraints on the values of the parameter \( n \).

With respect to pancytopenia and marrow hypoplasia the hypothesis offers the following quantitative predictions: (1) If it is desired to induce PH, then subjects with an initially low \( M^* \) will have a much higher probability of de-
veloping PH. The threshold $M^*$ for the induction of PH should be on the order of $3.7 \times 10^7$ cells/kg/day in man and $6.6 \times 10^7$ cells/kg/day for mongrel dogs. (2) In man and dogs treated with cycle-active agents PH is not expected to occur until $M^*$ has been depressed to about 30% and 40% of its mean values, respectively. Note, however, that this is a sufficient but not necessary requirement for the development of PH.35,36

Finally, the hypothesis predicts that the pluripotential stem cell population in aplastic anemia and periodic hematopoiesis will be characterized by an elevated proliferating fraction $F_p$ and by an elevated doubling time $t_D$ during exponential growth.

I would like to thank Professors B. Cooper, D. Dale, J. Dancey, and W. Hammond for their comments on this work, and I thank Christine Pamplin for her meticulous typing of the manuscript.

**APPENDIX 1. MODEL EQUATIONS**

In this appendix the equations describing the dynamics of the populations of proliferating- and $G_0$-phase stem cells are given without derivation, along with heuristic arguments for their structure. The derivation of the equations rests on a time-age formulation and utilizes techniques illustrated elsewhere.41 The parameters and functions appearing in the equations are defined below and discussed in the section entitled The Model.

**Symbols**

- $P(t)$, density (cells/kg) of proliferating phase stem cells as a function of time (days).
- $N(t)$, resting-phase ($G_0$) stem cell population density (cells/kg) as a function of time (days).
- $P^*$, steady-state proliferating-phase stem cell density (cells/kg).
- $N^*$, steady-state $G_0$-phase stem cell density (cells/kg).
- $T$, cell cycle time, or time spent by a cell in the proliferating phase (days).
- $M$, rate (days$^{-1}$) of differentiation out of the $G_0$ phase of the PPSC into the myeloid series. Subscript $E$ or $T$ denotes the analogous rates into the erythroid and thrombocyte series, respectively.
- $M^*$, total steady-state differentiation cellular flux (cells/kg/day) from the $G_0$ phase of the PPSC into all of the hematopoietic lines, $M^* = \delta N^*$.

**Model Equations**

The equation for the population $N(t)$ of resting $G_0$ phase cells is

$$\frac{dN}{dt} = -\delta N - \beta(N)N + 2\beta(N)N^* e^{-\gamma t}, \quad t < \tau,$$

where $N^* = N(t-\tau)$. Equation (1.1) equates the total rate of change of $N(t)$ with the sum of three terms. The first term on the right-hand side of (1.1) accounts for irreversible loss from the $G_0$ population due to differentiation; the second corrects for cell loss due to the movement of cells into proliferation; and the last term represents a cellular gain due to the movement of proliferating
cells into \( G_0 \) one generation time ago; the factor of 2 accounts for mitosis, and \( e^{-\gamma r} \) corrects for the probability of cellular loss from the proliferating population.

The dynamics of the population \( P(t) \) of cells in proliferation is described by

\[
\frac{dP}{dt} = -\gamma P + \beta(N)N - \beta(N_{i})N_{i} e^{-\gamma r}, \quad r < t. \tag{1.2}
\]

As before, the first term on the right-hand side of (1.2) is an irreversible-loss term, the second represents cellular entry from the \( G_0 \) phase, and the last accounts for the flux of cells from the proliferating to the nonproliferating phase one generation time previously.

The specific functional form chosen for \( \beta(N) \) is

\[
\beta(N) = \frac{\beta_0 \theta^N}{\theta^N + N^a}, \tag{1.3}
\]

where \( \beta_0 \) (days\(^{-1}\)), \( \theta \) (cells/kg), and \( a \) are parameters. The qualitative predictions of this model are independent of the form \( \beta \) takes as long as (1) \( \beta(N) \) is a smoothly decreasing function of increasing \( N \), (2) \( \beta \) has a finite maximum (e.g., \( \beta_0 \)), and (3) \( \beta \) has an adjustable inflection point (e.g., \( \theta \)) and adjustable slope (e.g., \( -n\beta_0/\theta \)).

The form for \( \beta(N) \) can be argued for as follows: Suppose each cell contains a receptor for a mitotic regulatory molecule. Suppose each cell contains a receptor for a mitotic regulatory molecule. When the receptor is in the uncombined form it is active in the sense that mitosis proceeds in a regular fashion, but when combined it is inactive or capable of preventing mitosis. Assume the following: (1) the reaction between receptor and regulator molecule proceeds according to \( M + nC \rightarrow L \), where \( M \) and \( L \) denote the active and inactive forms of the receptor and \( C \) is the regulatory molecule; (2) the equilibrium constant for the reaction is \( K \), so that

\[
\frac{[M]}{[L]} = K, \tag{1.4}
\]

where brackets denote a concentration; and (3) there are a fixed number of receptors \( T \) per cell, \( [T] = [M] + [L] \). Then the fraction of active receptors \( [M]/[T] \) will be given by \( K/[K + [C]^a] \). Assuming the number of regulatory molecules to be directly proportional to the number of \( G_0 \)-phase cells, \( [C] = dN \), and the maximal rate of entry into the cell cycle to be \( \beta_0 \), thus gives the form for \( \beta \) as shown in Eq. (1.3), where \( \theta^{-1} = aK^{1/a} \).

With this choice for the control function \( \beta \), the model is completely specified, and Eqs. (1.1) and (1.2) become, respectively,

\[
\frac{dN}{dt} = -\delta N + \frac{\beta_0 \theta^N N}{\theta^N + N^a} - \frac{2\beta_0 \theta^N N_e e^{-\gamma r}}{\theta^N + N^a}, \quad r < t, \tag{1.4}
\]

\[
\frac{dP}{dt} = -\gamma P + \frac{\beta_0 \theta^N N}{\theta^N + N^a} - \frac{\beta_0 \theta^N N_{i} e^{-\gamma r}}{\theta^N + N^a}, \quad r < t. \tag{1.5}
\]

### APPENDIX 2. PROPERTIES OF THE MODEL

Equations (1.4) and (1.5) have two sets of steady-state solutions \( P^* \) and \( N^* \) at which \( dP/dt = dN/dt = 0 \). The first is \( P^* = N^* = 0 \), and the second is

\[
N^* = \theta(\beta_0/\delta)(2e^{-\gamma r} - 1 - 1)^{1/\epsilon}, \quad P^* = N^*\left(\delta/\gamma(1 - e^{-\gamma r})/(2e^{-\gamma r} - 1)\right). \tag{2.1}
\]

\( P^* \) and \( N^* \) will be greater than zero only if

\[
0 < \gamma r < \ln\left(2\beta_0/\delta + \delta\right) < \ln 2. \tag{2.2}
\]

In the "normal" state there is no loss of cells from proliferation (\( \gamma = 0 \)). From (2.2) the limiting steady-state cellular populations in this case become

\[
N^* = \delta(\beta_0/\delta - 1)^{1/\epsilon}, \quad P^* = \delta r N^*, \tag{2.3}
\]

while the condition (2.2) becomes \( \delta(\beta_0/\delta) > 1 \).

The behavior of the model under mitotic regulatory control is not presently amenable to analytic description. What is possible is a discussion of the behavior near the steady-state cellular populations. Take the linear portion of (1.4) near any equilibrium point \( N^* \), with \( N(t) = \varepsilon(t) + N^* \), \( \varepsilon(t)/N^* \ll 1 \), to give the linear differential delay equation

\[
\frac{d\varepsilon}{dt} + A\varepsilon(t) + B\varepsilon(t - \tau) = 0, \tag{2.4}
\]
where \( A = \delta + \beta_0 F(N^*, n) \), \( B = -2\beta_0 F(N^*, n) e^{-\gamma} \), and
\[
F(N^*, n) = \frac{\theta^n (1 - n)(N^*)^n}{[\theta^n + (N^*)^n]^2}.
\]
Assume that (2.4) has a solution of the form \( e^{\lambda t} \), \( \lambda = \mu + j\omega \), \( j^2 = -1 \), and substitute into (2.4) to give
\[
\lambda + A + B e^{-\lambda t} = 0.
\]
(2.5)

Equate the real and imaginary portions of (2.5) to find
\[
\omega t < \cos^{-1}(-A/B),
\]
(2.6)
where \( \omega^2 = B^2 - A^2 \), \( |A/B| < 1 \), is a necessary and sufficient condition for \( \mu < 0 \). Equation (2.6) gives the requirement that the stem cell parameters must satisfy in order that small changes \( z(t) \) away from the steady state \( N^* \) will die out. When \( \mu = 0 \),
\[
\omega t = \cos^{-1}(-A/B),
\]
(2.7)
and periodic solutions, of period \( T = 2\pi/\omega \), appear.

At the first steady state, \( P^* = N^* = 0 \), \( F = 1 \) and conditions for very small proliferating and resting cellular populations to approach zero may be obtained. However, numerical solutions to (1.4) and (1.5) indicate that the cellular populations will never be zero unless they are zero initially.

At the nonzero steady state defined by (2.1), \( F \) is a complicated function. Generally speaking, an increase in any one of the five parameters \( \gamma, \delta, \beta_0, n, \) or \( r \) with the other four held constant may lead to the loss of stability at a steady state and the appearance of oscillatory cellular populations.

For large deviations away from the steady state, as well as for values of the parameters that do not satisfy (2.6), the behavior of the populations cannot be predicted from this analysis. To investigate further the properties of the model under these conditions, numerical solutions to (1.4) and (1.5) were computed using a predictor-corrector integration scheme with an integration step size of 0.01. Further decreases in the step size led to no changes in behavior.

Briefly, the results of approximately 360 computed solutions to (1.4) and (1.5) with a range of parameters and initial conditions indicate that (1) for \( \gamma, \delta, \beta_0, n, \) and \( r \) that satisfy (2.6), the cellular populations always approach the steady states defined by (2.1); (2) Eq. (2.7) accurately predicts the onset of stable periodic variations in \( P(t) \) and \( N(t) \) (the period of the oscillation is accurately given by \( T = 2\pi/\omega \), where \( \omega^2 = B^2 - A^2 \) and \( A \) and \( B \) are defined above); and (3) for values of the parameters such that \( \omega t > \cos^{-1}(-A/B) \), periodic solutions of a complex nature and aperiodic solutions may occur.

The nature of these complicated bifurcations in the dynamics of Eqs. (1.1) and (1.2) will be considered elsewhere.

APPENDIX 3. PARAMETER ESTIMATION

The estimation of parameter values is made difficult by the lack of any body of common data on normal and abnormal stem cell properties. There are a number of parameters and thus many ways of arriving at estimates for them based on the existing data. The following assumptions have been made:

1. In the normal state there is no irreversible cell loss from the proliferating phase (\( \gamma = 0 \)).

Note, however, that a number of pathologic situations may be characterized by loss from proliferation.

2. In the normal state the stem cell population is at a stable steady state defined by Eqs. (2.3).

With these two assumptions the expression for the proliferating fraction, \( F_P = P^*/(P^* + N^*) \), becomes \( F_P = \delta r/(1 + \delta r) \). Using triated thymidine (\( ^3 \)H-dt) technique data on normal steady-state adult mouse marrow and spleen, \( F_P \) is at most 0.10, from which \( \delta r = 1 \) = 0.11.

The rate of differentiation into the hematopoietic cells lines, \( \delta \), is made up of three components: \( \delta_M \), the rate of differentiation into the myeloid series; \( \delta_E \), the rate into the erythroid series; and \( \delta_T \), the rate into the thrombocyte series. To determine these individual contributions to \( \delta \), proceed as follows:
PERIODIC HEMATOPOIESIS
953

The granulocyte turnover rate (GTR) has been measured in man and dogs using initially \(^{32}P\) diisopropylphosphofluoridate (DF\(^{32}P\)) and more recently \(^{3}H\)-dt. The results obtained by the two methods are discrepant by a factor of approximately 0.5, and there is strong evidence that the \(^{3}H\)-dt estimates of GTR are more accurate.\(^{43,47}\) Assuming this to be the case, I have adopted the mean GTR estimates based on \(^{3}H\)-dt measurements: \(0.87 \times 10^6\) cells/kg/day for man, \(1.65 \times 10^6\) cells/kg/day for mongrel dogs. If there is no significant cell loss from the maturing nonproliferating granulocyte precursor compartments\(^{45,47}\) and from the proliferating compartments, then the steady-state GTR must be equal to the cellular flux into the myeloblast compartment \((\delta_{M} N^* )\) times the amplification in cell numbers due to proliferation in the myeloblast, promyelocyte, and myelocyte states \((2^n)\): GTR = \(2^n (\delta_{M} N^* )\) cells/kg/day. Summarized data\(^{41}\) on the relative frequencies of proliferating granulocyte precursor cells give \(m\) values ranging from 2.6 to 5.6, and I have adopted a value of \(m = 4\).

The total PPSC compartment for a 70-kg human has been estimated at \(5 \times 10^{10}\) cells, or \(P^* + N^* = 7.14 \times 10^7\) cells/kg.\(^{31}\) With a proliferating fraction of 0.10, this gives \(P^* = 0.71 \times 10^6\) and \(N^* = 6.43 \times 10^5\) cells/kg, in agreement with a previously determined\(^{31}\) lower bound on \(N^* \) of \(5 \times 10^5\) cells/kg.

With these considerations in mind, \(\delta_{M} \) is given by \(\delta_{M} = \text{GTR} \times 9.72 \times 10^{-11}\) (day\(^{-1}\)), where the GTR is given in units of cells/kg/day, to predict normal values of \(\delta_{M}\) for humans of 0.09/day and 0.16/day for dogs.

To obtain an estimate for \(\delta_{E}\), note that there are on the order of \(5 \times 10^9\) nucleated red blood cells in the marrow.\(^{48}\) The transit time through this compartment is about 180 hr,\(^{39}\) and it is estimated that there are about four mitoses in the nucleated red blood cells,\(^{50}\) so the cellular efflux from the normoblast compartment is \(2^n \delta_{E} N^*\), and the influx into that compartment from the PPSC is \(\delta_{E} N^*\). Thus in a steady-state situation in man \(\delta_{E}\) is about 0.07/day. It is not known if the elevated GTR in dogs is reflected in an elevated erythrocyte production rate relative to man. However, I assume here that it is and take \(\delta_{E} = 0.07\) day for normal humans and \(\delta_{E} = 0.07 \times (1.65/0.87) = 0.13\) day for mongrel dogs.

The rate \(\delta_{T}\) of differentiation into the thrombocyte line is derived from the observation that the megakaryocyte compartment in man is about \(6.1 \times 10^6\) cells/kg,\(^{31,52}\) and that the mean time spent in the megakaryocyte compartment is approximately 2.5 days.\(^{31}\) Thus the megakaryocyte production rate is \((6.1/2.5) \times 10^5 = 2.44 \times 10^5\) cells/kg/day. This must be equal to \(\delta_{T} N^*\), and thus in man \(\delta_{T} = 3.81 \times 10^{-1}\) (day\(^{-1}\)). As before, a value for dogs is derived from the human value: \(\delta_{T} = 7.23 \times 10^{-3}\) (day\(^{-1}\)).

These estimates predict a total rate of loss from \(G_0\) into the differentiated hematopoietic lines of \(\delta = 0.164\) day for normal humans and 0.297 day for normal dogs. Thus the total average cellular flux for each is \(M^* = 1.05 \times 10^6\) and \(1.91 \times 10^5\) cells/kg/day, respectively.

Having obtained \(\delta\), the cell cycle time \(\tau\) can be estimated directly from \(\delta \tau = \frac{1}{2}(\text{Fig. 3})\). Independent measures for \(\delta\) and \(\tau\) do not exist in the literature. However, other workers have estimated the cell cycle time at between 12 and 36 hr.\(^{34,57}\) The values for \(\tau\) corresponding to the calculated mean flux into differentiation for both man and dogs are in agreement with the estimates of these other workers.

The stability analysis of Appendix 2 indicates that if \(N^\star\) and \(P^\star\) are started near the nonzero steady states [Eqs. (2.1)] they will always return to \(N^\star\) and \(P^\star\) when (2.6) is satisfied. For small initial values \(N_0\) and \(P_0\), \((N_0/N^\star) \ll 1\) and \((P_0/P^\star) \ll 1\), the solutions will also ultimately approach \(N^\star\) and \(P^\star\). Computer solutions show that the growth characteristics of the stem cell populations under these conditions are typified by a period of exponential growth followed by a gradual slowing in the growth rate as the steady state is approached. These are the same growth properties noted in splenic colonies arising from the injection of marrow cells into irradiated recipients.\(^{32}\) From these observations, a simple analysis for deriving estimates for \(P_0\) from the exponential doubling time is possible.

For small values of \(N, N \ll \theta\), the nonlinear equations (1.4) and (1.5) may be approximated (see Appendix 2) by the pair of linear time-delay differential equations

\[
\frac{dN}{dt} = -(\delta + \beta_0)N + 2\delta_0 e^{-\gamma\tau} N_\tau, \quad \tau > t. \tag{3.1}
\]

\[
\frac{dP}{dt} = -\gamma P + \beta_0 N - \beta_0 e^{-\gamma\tau} N_\tau, \quad \tau > t. \tag{3.2}
\]
In keeping with observations from computer simulations, I assume \( N(t) \) to grow exponentially, \( N(t) = N_0 e^{\lambda t} \), where \( \lambda \) is the growth rate. Thus Eq. (3.1) reduces to

\[
\lambda + \delta + \beta_0 - 2\beta_0 e^{-(\gamma + \lambda) t} = 0. \tag{3.3}
\]

With \( N(t) = N_0 e^{\lambda t} \), Eq. (3.2) becomes a linear differential equation whose solution is

\[
P(t) = P_0 e^{-\gamma t} + (N_0 \beta_0 / \lambda) (e^{\lambda t} - 1) (1 - e^{-(\gamma + \lambda) t}). \tag{3.4}
\]

The doubling time for the cell population is defined as the time it takes \( P + N \) to become twice its initial value, or

\[
P(t_d) + N(t_d) = 2(P_0 + N_0). \tag{3.5}
\]

Set \( t = t_d \) in \( N(t) = N_0 e^{\lambda t} \) and Eq. (3.4) and substitute the results into (3.5) to give

\[
P_0 (2 - e^{-\gamma t_d}) = (1 - P_0) e^{\lambda t_d} + (\beta_0 / \lambda) (e^{\lambda t_d} - 1) (1 - e^{-(\gamma + \lambda) t_d} - 2). \tag{3.6}
\]

where I have made use of the relation

\[
\beta_0 = (\lambda + \delta) / (2e^{-(\gamma + \lambda) t_d} - 1). \tag{3.7}
\]

Equation (3.7) is a transcendental equation involving \( \beta_0, \gamma, t_d, F_p, \tau, \) and \( \lambda \). If values for \( t_d, F_p, \gamma, \) and \( \tau \) are available, then (3.6) contains only two unknowns, \( \beta_0 \) and \( \lambda \). Rewrite (3.3) as

\[
\beta_0 = (\lambda + \delta) / (2e^{-(\gamma + \lambda) t_d} - 1)
\]

and substitute the result into (3.6) to obtain a transcendental equation in \( \lambda \) alone, with \( \delta \) known, that may be numerically solved. Having once obtained a value for \( \lambda \) by this procedure, \( \beta_0 \) is directly available from Eq. (3.8).
