Leukemic Blast Cell Colony Formation in Semisolid Culture With Erythropoietin: A Case Report of Acute Poorly Differentiated Erythroid Leukemia

By Masao Tomonaga, Itsuro Jinai, Masuko Tagawa, Tatsuhiko Amenomori, Kenji Nishino, Eiichi Yao, Hiroaki Nonaka, Kazutaka Kuriyama, Yoshiharu Yoshida, Tatsuki Matsuo, Michito Ichimaru, and Tadashi Suematsu

The bone marrow of a patient with acute undifferentiated leukemia developed unique colonies after a 14-day culture in erythropoietin (EPO)-containing methylcellulose. The colonies consisted of 20 to 200 nonhemoglobinized large blast cells. Cytogenetic analysis of single colonies revealed hypotetraploid karyotypes with several marker chromosomes that were identical to those found in directly sampled bone marrow. The concurrently formed erythroid bursts showed only normal karyotypes. No leukemic colony formation was observed in other culture systems with tinin-stimulated leukocyte-conditioned medium (PHA-LCM). The leukemic colonies exhibited a complete EPO-dose dependency similar to that of the patient's normal BFU-E. Although cytochemical and immunologic marker studies of the bone marrow cells failed to clarify the cell lineage of the leukemic cells with extraordinarily large cell size, ultrastructural study revealed erythroid differentiation such as siderosomes that were identical to those found in directly sampled bone marrow. Cytogenetic analysis of single colonies revealed hypotetraploid karyotypes with several marker chromosomal aberrations. These findings indicate that the patient had poorly differentiated erythroid leukemia and that some of the clonogenic cells might respond to EPO in vitro. Corresponding to this biological feature, the leukemic cells were markedly decreased in number in response to repeated RBC transfusions, and partial remission was obtained. These observations suggest that erythroid leukemia distinct from erythroleukemia (M6) with a myeloblastic component, can develop as a minor entity of human acute leukemia.

EUKEMIC CELLS from patients with acute myeloid leukemia (AML) can form colonies composed of leukemic blasts in semisolid medium containing colony-stimulating factor (CSF)1,2 or phytohemagglutinin-stimulated leukocyte-conditioned medium (PHA-LCM).3 Izaguirre and colleagues also developed a culture method containing PHA-stimulated T cell-conditioned medium (TCM) and obtained leukemic colonies from patients with either AML or ALL.4 The clonogenic cells in these leukemic colonies were designated leukemic colony-forming units (L-CFU).4-10 Among various biological features of L-CFU so far elucidated, especially in the PHA-LCM system, self-renewal function as measured by secondary plating efficiency (PE2) appears to be of special importance because it defines the stem cell nature of at least a part of these cells.11,12 In this article, we describe the first instance of leukemic blast cell-colony formation in erythropoietin (EPO)-containing methylcellulose culture from a patient with acute undifferentiated leukemia with ultrastructural evidence of erythroid differentiation and distinct chromosomal aberration.

MATERIALS AND METHODS

Case Report

The patient, a 50-year-old man, was admitted to a local hospital on September 10, 1983, because of a heel bone fracture. No abnormality was found in his peripheral blood, but pancytopenia developed rapidly during the next 2 months. He was transferred to our department on November 21, 1983. On admission, he was anemic and appeared acutely ill. No lymphadenopathy or splenomegaly was found. The liver was palpated 3 cm below the right costal margin. The hemoglobin (Hb) level was 5.8 g/dL. The WBC count was 3.6 x 10⁶/L with 52% mature neutrophils, 40% lymphocytes, 2% eosinophils, and 6% monocytes. The platelet count was 41 x 10⁹/L. Initial bone marrow aspirate was highly cellular, with 31.6% abnormal blast cells, 1.0% myeloblasts, 5.9% promyelocytes, 6.8% myelocytes, 7.4% metamyelocytes, 32.8% mature neutrophils, 1.6% pronormoblasts, and 2.8% normoblasts. Megakaryocytes were decreased in number. The abnormal cells were extraordinarily large (30 to 40 μm in diameter), had a finely reticulated chromatin pattern, and moderate to strongly basophilic cytoplasm with some vacuoles but no granules (Fig 1). A few cells resembled pronormoblasts and some showed dense cytoplasmic staining. The patient was given 3 U of packed RBC for the next 3 days and recovered. After this transfusion, peripheral blood findings improved and were stable for ~40 days with Hb 8.3 g/dL and WBC 4.55 x 10⁹/L. Bone marrow aspiration was then performed, with a marked reduction of abnormal cell percentage to 3.4%, and erythroblasts were elevated to 65.6% (December 20, 1983). On January 6, 1984, however, leukemic cells in the bone marrow again increased to 30%. A low-dose cytosine arabinoside (ara-C) regimen (10 mg/day, continuous intravenous (IV) infusion for 16 days) was begun. A partial remission, with <5% abnormal cells, was obtained (February 8, 1984), but the leukemic cells began to increase again (February 20, 1984). The patient was further treated with the same regimen for 32 days. A second partial remission was obtained (April 10, 1984) but was transient, with a resultant increase of leukemic cells to 10% (April 24, 1984). A more intensive chemotherapy with ara-C and daunorubicin did not induce remission, and the leukemic cell proliferation became extensive, with rapidly increasing hepatosplenomegaly. The patient soon died of pneumonia and intestinal bleeding.

ACUTE ERYTHROID LEUKEMIA

547
detected by indirect immunofluorescence using anti-TdT antibody. Bone marrow cells were aspirated and transferred into a droplet (10 μL) of prewarmed 0.075 mol/L of KCl solution placed on a poly-L-lysine-coated slide. (Sigma Chemical, St Louis). After thorough mixing, the slide remained for 35 minutes at 37°C to allow the cells to attach. The slide was fixed, first with 30% fixative (3:1 methanol:acetic acid diluted with 0.075 mol/L of KCI), second with 20% ethanol diluted with 0.075 mol/L of KCI, and third with 100% fixative. The slide was then flame-dried and stained with Giemsa and/or Q-banded. This method yielded analyzable metaphases even from small colonies containing <40 cells. All laboratory examinations and in vitro assays were performed with informed consent from the patient.

RESULTS

Cytological Features of the Leukemic Cells

The undifferentiated, extraordinarily large leukemic cells were MPO−, both types of esterase−, acid phosphatase− (86%), β-glucuronidase−, PAS−, and Hb−. They were also ultrastructurally MPO−. Immunological marker study disclosed CALLA−, Leu 1−, TdT−, OKM1−, and HLA-DR− (12%). Transmission electron microscopic examination revealed distinct siderosome formation in the cytoplasm of <5% of the leukemic cells and fairly abundant rhopheocytotic invaginations and vesicles containing ferritin particles in half of the leukemic cells (Fig 2A, B, C).

Cytogenetic Findings in Bone Marrow Cells

Results of the serial cytogenetic studies are shown in Table 1. Abnormal hypotetraploid karyotypes were found on initial examination. Most of them had several identical marker chromosomes (Fig 2A). Repeated examinations revealed a considerable karyotypic instability (data not shown). Normal karyotypes were also present, but as a minor population. During the first partial remission, a clone with hypodiploid karyotypes was also observed. The relationship of the hypodiploid clone to the hypotetraploid clone could not be clearly explained. The hypotetraploid clone may represent the giant leukemic blast cells because they are known to have an excess amount of chromosomal materials.

Leukemic Blast Cell Colony Formation in EPO-Containing Culture

Erythroid colony assay of the bone marrow performed at the time of partial remission (January 6, 1984) disclosed bizarre colonies (Fig 3) consisting of 20 to 200 large nonhemoglobinized cells as well as well-hemoglobinized erythroid burst formation (Table 2). These two types of colonies reached maximum number on day 14 and did not form a single mixed colony. The cells from the bizarre colonies were uniformly large blast cells on MG-stained cytospin-smears.
Fig 3. Leukemic blast cell colony observed in day 14 erythropoietin containing culture shows an aggregation of large nonhemoglobinized cells (original magnification x200).

and resembled the leukemic cells in the bone marrow. They were negative for Hb, dual-esterase, and MPO stains. Cytogenetic analysis from individual day 14 colonies including normal-appearing erythroid bursts obtained from the relapsing bone marrow (February 20, 1984) was performed (Table 3). Karyotypes from the bizarre colonies revealed hypotetraploidy with several identical marker chromosomes, indicating that they belonged to a single abnormal clone (Fig 4B). Furthermore, these karyotypes carried marker chromosomes identical to those observed in the hypotetraploid karyotypes of the directly sampled bone marrow (Fig 4A). In contrast, karyotypes from erythroid bursts were all normal, showing 46, XY.

No leukemic colony formation was observed after culturing with GCT-CM or PHA-LCM. The data of serial colony assays are summarized in Table 2. The numbers of CFU-GM and erythroid bursts had recovered considerably at the time of partial remissions.

EPO-Dose Response by L-CFU

Figure 5 shows the EPO-dose–response curves for leukemic colonies and erythroid colonies from the bone marrow.
specimen obtained on April 24, 1984. The response curve of L-CFU was similar to those of CFU-E and BFU-E but appeared to be slightly higher at EPO concentration of 0.1 U/mL. A few leukemic colonies with <30 cells developed spontaneously without EPO.

**DISCUSSION**

The extraordinarily large leukemic blast cells of this patient lacked evidence of differentiation toward specific cell lineage on conventional cytochemical and cell surface marker analyses. Ultrastructural investigation demonstrated, however, at least in some of the leukemic cells, distinct siderosome formation in the cytoplasm and ferritin droplets. These findings provide evidence of erythroid differentiation.28-34 These markers were also demonstrated, however, on AML blasts35 and K562 cells with simultaneous expression of myeloid antigen.36 Therefore, combined ultrastructural and immunological analyses of future cases of undifferentiated leukemia must be conducted to clarify the kind of markers that provide the earliest and consistent evidence of erythroid differentiation in leukemic cells.

The bizarre nonhemoglobinized colonies that developed concurrently with the patient’s normal erythroid bursts in EPO-containing culture apparently derived from the leukemic clone, as evidenced by the presence in single colonies of a common karyotypic abnormality identical to that of the leukemic clone in the bone marrow. The L-CFUs from our patient did not develop colonies in other culture systems with GCT-CM or PHA-LCM, indicating that the L-CFUs responded to EPO itself in the culture medium. There remains a minor possibility of response to another activity, however, such as burst-promoting activity (BPA) contaminating the partially purified EPO material. We found no report of leukemic blast cell colony formation in BFU-E assay or leukemic colonies expressing erythroid markers in other culture systems.

Clonal culture studies in acute erythroleukemia (M6) are also few.37-39 clinical and hematologic features common to these cases are (a) relatively advanced age (>50 years), (b) poor response to conventional chemotherapy, (c) low WBC count with minimal or absent leukemic blasts in the peripheral blood, (d) extraordinarily large leukemic cells, (e) high ploidy and instability of karyotype, (f) ultrastructural evidence of erythroid differentiation and (g) lack of simultaneous proliferation of peroxidase-positive myeloid precursor cells. These characteristics suggest the possibility that this type of acute leukemia is a clinical entity distinct from erythroleukemia (M6) with a myeloblastic component,27 and may be a poorly differentiated type of acute erythremia.28-31

It is not yet clear whether the immunologic markers of erythroid differentiation such as glycoporphin A and spectrin can be demonstrated on these poorly differentiated leukemic cells. Detection of such markers using monoclonal or heterologous antibodies may reveal an erythroid nature of undifferentiated leukemia.28-32 These markers were also demonstrated, however, on AML blasts33 and K562 cells with simultaneous expression of myeloid antigen.36 Therefore, combined ultrastructural and immunological analyses of future cases of undifferentiated leukemia must be conducted to clarify the kind of markers that provide the earliest and consistent evidence of erythroid differentiation in leukemic cells.

†All metaphases were photographed and karyotyped.
‡Aspiration of each colony was performed on day 14 of culture. L-CFU: leukemic colony-forming unit.
Fig 5. Erythropoietin (EPO) dose–response curves. The response curve of leukemic colony forming unit (□) is similar to those of normal BFU-Es (□) and CFU-Es (▲), but the L-CFUs show a slightly higher sensitivity to EPO at the lowest concentration of 0.1 U/mL. A few small leukemic colonies developed without EPO. The colony numbers at EPO 1.0 U/mL were regarded as 100%.

dose–response curve was similar to those of the patient’s own normal BFU-Es and CFU-Es, but the L-CFUs showed a slightly higher sensitivity at the lowest dose of EPO. Theoretically, this hypersensitivity may explain the in vivo growth advantage of the leukemic clone over the normal erythroid progenitors. The reduction of the leukemic cell number in the bone marrow was rapid and marked after repeated transfusions, suggesting that a kind of feedback phenomenon occurred and induced a clinical partial remission without the use of chemotherapeutic agents. This observation indirectly supports the view that the leukemic cell proliferation in vivo was at least in part dependent on a given concentration of EPO. The feedback phenomenon in our patient mimics the marked erythroid depression inducible in patients with erythroleukemia by hypertransfusion.39–41
