Immunoglobulin G Subclass Deficiency and Pneumococcal Infection After Allogeneic Bone Marrow Transplantation

By John F. Sheridan, Peter J. Tutschka, Daniel D. Sedmak, and Edward A. Copeland

Serum immunoglobulin (Ig) G subclass levels were measured in a radial immunodiffusion assay in 25 leukemic patients before and after allogeneic bone marrow transplantation. All patients received a conditioning regimen of busulfan and cyclophosphamide followed by infusion of marrow from an HLA-identical sibling. Intravenous infusions of a commercial Ig preparation were administered every 2 weeks until day 120 posttransplant. Nine patients developed pneumococcal infections at 6 months or greater posttransplant. Infestation was associated with low levels or the absence of detectable serum IgG2 and IgG4. At the time of infection, 4 of 7 patients evaluated had undetectable IgG2, while 5 of 7 had undetectable levels of IgG4. After infection, none of the 8 patients evaluated had detectable levels of IgG2, and only 2 of 8 had detectable levels of IgG4. In contrast, all 16 patients without pneumococcal infection had IgG2 levels of 102 mg/dL or greater, and IgG4 levels of 20 mg/dL or greater. It appears that IgG2 and IgG4 subclass deficiencies after allogeneic bone marrow transplantation contribute to susceptibility to pneumococcal infection. After pneumococcal infection, IgG2 and IgG4 levels remain low for a prolonged period and patients remain susceptible to infection by encapsulated organisms.

immunodiffusion plate contained a monospecific sheep anti-human antiserum in agarose. Monospecificity was achieved by adsorbing the antiserum against other IgG subclasses. Briefly, serum samples were diluted in sheep serum, and three standards were applied in antiserum in agarose. Monospecificity was achieved by adsorbing the antiserum. Serum samples were diluted and repeated. The lower level of sensitivity for each plate was generated by plotting the squares of the standard precipitation ring diameter versus their concentration in milligrams per liter.

Statistical methods. Linear regression was used to estimate the relationship between time after bone marrow transplantation (BMT) and serum Ig subclass levels. For subclass levels the data are presented as geometric mean titers (GMT) and 95% confidence intervals (lower limit, upper limit). Fisher's exact test was used to detect subclass differences between the infected and noninfected patient groups.

RESULTS

Nine patients developed late (more than 6 months) pneumococcal infections after ABMT (Table 1). All 9 developed pneumonia; 3 were bacteremic, and 3 patients also had sinusitis (patients 2, 3, and 8) or otitis media (patient 2). Four patients developed second, and two patients developed third, episodes of pneumonia with either St. pneumoniae or H. influenzae (patients 4, 5, 6, and 8). Five of these 9 patients had chronic GVHD, which was extensive in 3 patients and limited in 2 patients at the time of initial infection. The three patients with extensive chronic GVHD were taking methylprednisilone, azathioprine, and trimethoprim-sulfamethoxazole at the time of infection; however, at least one of the patients frequently skipped doses of trimethoprim-sulfamethoxazole. None of these patients were taking any other antibiotic. None of the nine patients had experienced acute GVHD of grade II or greater. Serum Ig classes were measured at the time of the first pneumococcal infection in seven patients with pneumonia (median time from transplantation was 228 days). IgG levels were normal for 4 of 7 patients, IgM levels were normal for 5 of 7 patients, and IgA levels were low in all 7 patients tested (Table 1).

Serum IgG subclass levels were also measured in the infected and control patients; however, serum samples were not available for every patient for each time period. Serum levels of IgG1 and IgG3 changed only slightly during the course of observation (Table 2). The differences in IgG1 and IgG3 between the infected group and noninfected control group were not statistically significant at any point in time. IgG2 levels declined with time after transplantation in both groups. Among nine noninfected patients who were sampled in each of the four time periods (pre-BMT, and days 96, 204, and 560 after BMT), the regression coefficient of the IgG2 level to the sampling times was -152.9 and was highly significant (P = .001). In the infected group, the geometric mean titer for IgG2 was 94 mg/dL before transplantation and declined sharply after infection. While the sample size was too small for a regression analysis, IgG2 titers in the patients with infections were significantly lower than in the uninfected patients (Table 2). On the other hand, serum IgG4 levels showed little variation in the noninfected group but did decline significantly in the infected group (Table 2).

Normal Ig concentrations (mg/dL, range): IgG, 600 to 1,200; IgA, 150 to 350; IgM, 75 to 150.

Abbreviations: CML, chronic myelogenous leukemia; AML, acute myelogenous leukemia; St pn, Streptococcus pneumonia; H infl, Hemophilus influenzae; ND, not done.
The regression coefficient for the infected group was $-53.6$ with a $P < .05$. The percent decline of IgG4 between the time intervals of the study was 62% for the "pre-BMT" samples compared with the "before infection" samples, 46% for the "before infection" to "during infection," and 57% for the "during infection" samples to the "postinfection" samples. Thus, patients with pneumococcal infections were those with combined IgG2 and IgG4 deficiency.

There also appeared to be an effect of infection on antibody subclass levels. Infection occurred long after IV Ig therapy was discontinued (median day during infection was 228 after transplant, while IV Ig was discontinued on day 120 after marrow transplant). At the time of infection, 4 of the 7 patients had undetectable IgG2, and 3 patients had low but detectable levels of IgG2 antibody ranging from 120 to 157 mg/dL (Fig 1). None of the seven patients evaluated had detectable IgG2 at a median of 160 days after initial infection. In addition, only 2 of 7 infected patients had detectable IgG4 antibody during and after infection (compared with 15 of 16 noninfected patients that had detectable levels of IgG4).

**DISCUSSION**

This study confirms the previously described existence of a long-lasting IgG subclass deficiency after ABMT\(^4\) and shows that these humoraly deficient patients are susceptible to recurrent respiratory infections caused by *S pneumoniae*. In prior studies demonstrating the existence IgG subclass deficiency after bone marrow grafting, patients were conditioned for transplantation with a combination of drugs (cyclophosphamide\(^2\) or busulfan\(^3\)) and total body irradiation. In this study, total body irradiation was not a part of the conditioning regimen. It is clear that the inclusion of total body radiation in the preparative regimen is not responsible for subclass deficiency after BMT.

More than one mechanism for subclass deficiency may exist in patients who develop bacterial infections. One group (three of the infected patients) had a preexisting deficiency of IgG2 before transplantation, and the deficiency was not corrected in the year after BMT, suggesting that the underlying disorder or previous therapy was responsible for the deficiency. The second group was making detectable levels of IgG2 before BMT and before infection, but ceased to make it after resolution of the infection. In these individuals, bone marrow allografts did not replenish the ability of the host to make Ig of the IgG2 and IgG4 subclasses. Speculation as to the mechanisms operative in the development of this subclass deficiency includes a lack of sufficient T-cell help\(^2\) for IgG2/IgG4 production as a consequence of the disordered reconstitution of T-cell subsets, and a long-lasting deficit of functional T-cell precursors.\(^12\)

Two discernible patterns of IgG subclass production were

![Fig 1. Individual serum IgG2 and IgG4 subclass levels from BMT patients with bacterial infections and noninfected control BMT patients. For patients with infections, samples were assayed during infection (O) or post infection (■). Noninfected patient samples were assayed during the same periods post transplantation. The median time post BMT for the "during infection" sample was 7.6 months, while the "postinfection" sample was collected 12.9 months after transplantation.](image-url)
apparent after transplantation. One group of patients had detectable levels of IgG2 and IgG4, while the second was deficient for IgG2 and IgG4. This latter population appears to be at risk for the development of respiratory infections caused by pneumococcus. This premise is supported by the clinical observation of the second and third episodes of infections by encapsulated bacteria in four patients who remained IgG2- and IgG4-deficient. It is clear that patients with IgG2 and IgG4 deficiencies after marrow transplant are at an increased risk of infection by encapsulated organisms.

Preliminary trials with IV Ig in children with selective IgG2 deficiency have suggested clinical effectiveness. In addition, recent studies have demonstrated that Ig infusions after marrow transplantation reduce the incidence of septicemia and may reduce the frequency of all forms of serious infections. Whether patients who are subclass-deficient after transplantation are specifically benefitted has not been clarified, but would be of particular interest. In addition, the clinical resistance of pneumococci to trimethoprim-sulfamethoxazole in our patients and in other studies suggests that this may be an inadequate form of pneumococcal prophylaxis in susceptible individuals.
