Chemokines play a central role for lymphocyte trafficking and homing. The mechanisms that direct the tissue localization of B cells from patients with chronic lymphocytic leukemia (B-CLL) are unknown. We found that CLL B cells express functional CXCR4 receptors for the chemokine stromal cell-derived factor-1 (SDF-1), as demonstrated by receptor endocytosis, calcium mobilization, and actin polymerization assays. Moreover, CLL B cells displayed chemotaxis to this chemokine that could be inhibited by monoclonal antibodies (MoAbs) against CXCR4, pertussis toxin, or Wortmannin, a phosphatidylinositol 3-kinase inhibitor. That this chemotaxis may be involved in the homing of CLL cells is argued by studies in which CLL B cells were cocultured with murine marrow stromal cell line that secretes SDF-1. Within 2 hours, CLL B cells spontaneously migrated beneath such stromal cells in vitro (pseudoperoxisis). This migration could be inhibited by pretreatment of CLL B cells with anti-CXCR4 MoAbs, SDF-1α, or pertussis-toxin. Furthermore, we noted strong downmodulation of CXCR4 on CLL B cells that migrated into the stromal cell layer. These findings demonstrate that the chemokine receptor CXCR4 on CLL B cells plays a critical role for heterotypic adherence to marrow stromal cells and provide a new mechanism to account for the marrow infiltration by neoplastic B cells.

Materials and Methods
Chemokines, antibodies, flow cytometry. Synthetic, human SDF-1α (1-67) was provided by Dr. I. Clark-Lewis (University of British Columbia, Vancouver, BC).
Columbia, Vancouver, Canada) and purchased from Upstate Biotechnol-
ogy (Lake Placid, NY). The following monoclonal antibodies (MoAbs)
specific for human surface antigen were used: anti-CXCR4–
phycocerythrin (PE) (12G5), anti-CD3–fluorescein isothiocyanate (FITC),
anti-CD19–allophycocyanin (APC), anti-CD49d, anti-CD40, anti-
CD54, and the appropriate isotype controls from Pharmingen (San
Diego, CA). The National Institutes of Health (NIH) AIDS research and
reference reagent program (Rockville, MD) provided the nonconju-
gated CXCR4 MoAb 12G5 and the CCR3-specific MoAb 7B11. For
flow cytometry, the cells were adjusted to a concentration of 5 × 10^6
cells/mL in RPMI 1640 with 0.5% bovine serum albumin (BSA). A total
of 5 × 10^5 cells were stained with saturating antibody concentrations
for 30 minutes at 4°C, washed 2 times, and then analyzed on a
FACSCalibur (Becton Dickinson, Mountain View, CA). Flow cytome-
try data were analyzed by using the FlowJo 2.7.4 software (Tree Star,
Inc, San Carlos, CA).

Cell purification, cell lines. After informed consent, blood samples
were obtained from patients fulfilling diagnostic and immunopheno-
typic criteria for common B-cell CLL at the University of California,
San Diego (UCSD) Medical Center. Blood mononuclear cells (PBMC)
were isolated via density gradient centrifugation over Ficoll Paque
(Pharmacia, Uppsala, Sweden). Cells were used fresh or viably frozen
in fetal calf serum (FCS) plus 10% dimethyl sulfoxide (DMSO) for
storage in liquid nitrogen. Frozen cells were cultured overnight at 37°C
in 5% CO_2 in air. Cells were washed with a 20-fold volume of ice-cold
penicillin-streptomycin-glutamine (GIBCO-BRL, Grand Island, NY).
Fluorescence-activated cell sorting (FACS) analysis of the CLL cells showed
an average of 93.1% ± 4.4% (mean ± standard deviation [SD]) CD19-
positive cells, representing the CLL B cells. The T cells are the second
most predominant population in the blood lymphocyte population of
CLL patients. These cells constituted an average of 3.9% ± 21.3
(mean ± SD, n = 16) of the total lymphocytes of all patient samples
examined. The viability of the CLL cells was always greater than 85%,
as determined by staining with propidium iodide (PI). The human pro-B
cell line, Reh, and the pre-B cell line, Nalm-6, were provided by Dr J.
Scheele (Department of Biochemistry and Chemistry, UCSD). The
murine stromal cell line M2-10B4 was purchased from the American
Type Culture Collection (ATCC: Rockville, MD). Cell lines were cultured
at 37°C in RPMI-1640 supplemented with 10% FCS and penicillin-streptomycin-glutamine (GIBCO-BRL).

CXCR4 reverse transcriptase-polymerase chain reaction (RT-PCR)
analysis. RNA was isolated from nonpurified (n = 12) or CD19-
selected CLL PBMC (n = 3), using the Quigen RNeasy kit (Quigen,
Santa Clarita, CA). RNA then was used for first strand cDNA synthesis
with the SuperScript preamplification system (GIBCO-BRL, Rockville,
MD), according to the manufacturer’s instructions. The following
CXCR4-specific primers were used: 5’ primer: GGA GAA TTC TTA
CCA TGG AGG GTA CCA TAC; 3’ primer: GGA GAA TTC AGC TGG
ATG GAA AAC ATG. The annealing temperature was 58°C and the
reaction proceeded for 35 cycles. To normalize for the amount of RNA,
we performed RT-PCR for human glyceraldehyde-3-phosphate dehydro-
genase (G3PD), as described.25

CXCR4 receptor endocytosis assay. Receptor downmodulation of
CXCR4 by SDF-1α was performed as described.26 Briefly, CLL cells, the
pro-B cell line, Reh, or the pre-B cell line, Nalm-6, each were adjusted to
5 × 10^6/mL in RPMI-1640 with 0.5% BSA. The cells were cultured
with SDF-1α at various concentrations for 1 hour at 37°C in
5% CO_2 in air. Cells were washed with a 20-fold volume of ice-cold
buffer without FCS, stained at 4°C with saturating concentrations of
PE-conjugated anti-CXCR4 MoAb, and then analyzed by flow cytome-
try.

Ca^2+ mobilization. Ca^2+ mobilization in response to SDF-1α was
performed as described.28 Briefly, the cells were loaded with Indo-1 AM
(Molecular Probes, Eugene, OR), washed 2 times with Ca^2+-free
modified Gey’s buffer (MGB), suspended in MGB containing 1.5
mmol/L Ca^{2+}, and then warmed to 37°C for 2 minutes in a stirred
vortex. The emission ratio at 400/480 nm was followed kinetically after
addition of the chemokine on an SLM 8000 fluorometer (Spectronic
Instruments, Inc, Rochester, NY). To induce maximal Ca^{2+} release,
cells were subsequently stimulated with 2.5 μg/mL ionomycin (Sigma
Chemicals Co, St Louis, MO).

Actin polymerization assay. Actin polymerization was tested as described.5,29 Briefly, cells (1.25 × 10^6/mL) were suspended in RPMI-1640 medium with 0.5% BSA at 37°C and incubated with 100
ng/mL SDF-1α for varying amounts of time. To determine actin
polymerization in CLL B cells, CLL cells were prelabeled with
anti-CD19 MoAb. At the indicated time points, 400 μL of the cell
suspension were added to 100 μL of a solution containing 4 × 10^{-7}
moL/FITC-labeled phallolidin, 0.5 mg/mL 1-α-lysophosphatidylchol-
one (both from Sigma), and 18% formaldehyde in phosphate-buffered
saline (PBS). The fixed cells were analyzed by flow cytometry on a
FACS Calibur and all time points are plotted relative to the mean relative
fluorescence of the sample before addition of the chemokine.

Chemotaxis assay. The chemotaxis assay across bare polycarbonate
was performed as described.5 Briefly, CLL cells or B-cell lines were
suspended in RPMI-1640 with 0.5% BSA. A total of 100 μL, containing
5 × 10^5 cells, was added to the top chamber of a 6.5-mm diameter
Transwell culture inserts (Costar, Cambridge, MA) with a pore size of
5 μm. Filters then were transferred to wells containing medium with or
without SDF-1α. The chambers were incubated for 2 hours at 37°C in
5% CO_2. After this incubation, the cells in the lower chamber were
suspended and divided into aliquots for counting with a FACS Calibur
for 20 seconds at 60 μL/min in triplicates or for immunophenotyping.
A 1:20 dilution of input cells was counted under the same conditions.
Antibody inhibition was performed by preincubating the cells with
different concentrations of anti-CXCR4 MoAb 12G5 or anti-CCR3
MoAb 7B11 for 30 minutes at 4°C before use in the chemotaxis assay.
For pertussis toxin treatment, cells were preincubated with 200 ng/mL
pertussis toxin (List Biological Laboratories, Inc, Campbell, CA) at
37°C for 2 hours, washed twice, and subsequently applied to the top
chamber of the chemotaxis assay. For inhibition of phosphatidylinositol
3-kinase (PI-3 kinase), B-CLL cells were incubated with different
concentrations of Wortmann (Calbiochem, San Diego, CA) at 37°C
for 30 minutes and then examined for chemotaxis in response to 100
ng/mL SDF-1α, as described above.

SDF-1 expression by the murine M2-10B4 marrow stromal cell line.
For SDF-1 mRNA detection, RNA was extracted from the M2-10B4
stromal cell line and used for cDNA synthesis as described above.
The sequences of the murine SDF-1β-specific primers we used were: 5’
primer: CCT AAG TCG TTA CCA TGG AGG GTA CCA TAC; 3’ primer:
CCT ATC TCG AGT CAC ACC TCT CAC ATC. The conditions of the
PCR reaction were the same as described above. A sequenced plasmid
containing the murine SDF-1β cDNA was used as a positive control.
Conditioned medium from this cell line was used to assay for secretion
of bioactive SDF-1. For this purpose, the culture medium was replaced
with serum-free medium (X-VIVO 15, Bio Whittaker, Walkersville,
MD) when cells had reached 70% confluency. After 3 days, the
conditioned medium was removed and used for chemotaxis and
receptor-endocytosis assays with the pro-B cell line, Reh, as described
above. For blocking of the CXCR4 receptor, Reh cells were preincu-
bated with 30 μg/mL anti-CXCR4 MoAb before being applied to the
chemotaxis chambers.

In vitro migration assay of CLL cells beneath stromal cells (Pseudo-
emperipolesis). To determine the role of SDF-1 in the interaction of
CLL cells with stromal cells in vitro, we developed an assay that allows
us to count and phenotype the cells that migrate into a stromal cell layer.
The murine stromal cell line M2-10B4 was seeded the day before the
assay onto collagen-coated 24-well plates at a concentration of 1.5 ×
10^6 cell per well in RPMI-1640 supplemented with 10% FCS and
penicillin-streptomycin-glutamine. CLL cells were suspended in RPMI-
1640/10% FCS and added to the stromal cell layer. The plates were incubated at 37°C in 5% CO₂. After incubation for 2 hours or at the indicated time points in the time course experiment, cells that had not migrated into the stromal cell layer were removed by vigorously washing the wells with RPMI medium 3 times. The complete removal of nonmigrated cells and the integrity of the stromal cell layer containing transmigrated cells was assessed by phase contrast microscopy and documented photographically. The stromal cell layer containing transmigrated cells was detached by incubation for 1 minute with trypsin/EDTA solution prewarmed to 37°C (ATV solution; Gibco-BRL). Cells were then immediately suspended by adding 1 mL ice-cold RPMI/10% FCS, washed, and suspended in 0.5 mL cold medium for counting by flow cytometry or staining of aliquots for flow cytometry. A lymphocyte gate was set using the different relative size and granularity (forward scatter and side scatter) characteristics to exclude stromal cells from the counts. Duplicate samples were counted at high flow for 20 seconds to determine the relative number of migrated cells. Control samples, in which 1 × 10⁶ CLL B cells were added to the wells immediately before the washing step, or samples that only contained stromal cells consistently had counts <200 events/20 seconds (background). To calculate the percentage of CLL cells that had migrated into the marrow stromal cells (MSC) layer, a 1/10 diluted sample of the input cell suspension was counted under the same conditions. For the analysis of the phenotype of the transmigrated CLL B cells, cells were costained with anti-human CD19 MoAb along with anti-CXCR4, anti-CD49d, anti-CD49e, anti-CD54, or anti-CD3 MoAbs. For the antibody inhibition studies, CLL cells were preincubated with 30 µg/mL anti-CXCR4 MoAb (12G5) for 30 minutes, washed twice, and applied to the assay. SDF-1 pretreatment was performed by preincubating CLL cells (1 × 10⁶ cells/mL) with synthetic SDF-1α at a concentration of 200 ng/mL for 1 hour at 37°C in 5% CO₂, before adding the SDF-1α containing CLL cell suspension to the assay. Pertussis toxin pretreatment was performed as described above.

Data analysis, statistics. Results are shown as mean ± standard deviation (SD) or standard error about the mean (SEM) of at least 3 experiments each. For statistical comparison between groups, the Student paired t-test or Bonferroni t-test were used. Analyses were performed using the Biostatistics software developed by Stanton A. Glantz (UC San Francisco). Flow cytometry data were analyzed using the FlowJo software.

RESULTS

Expression of CXCR4 mRNA and surface protein in B-CLL. We detected CXCR4 mRNA in 12 of 12 CLL blood samples tested (Fig 1A). The amount of CXCR4 mRNA detected did not vary if the CLL B cells were purified to greater than 98% purity before RNA extraction. RT-PCR for the GA3PD gene indicated that the samples contained similar amounts of RNA (data not shown).

We stained CLL blood cells with anti-CD3–FITC, anti-CXCR4–PE, and anti-CD19–APC, and examined for B- and T-cell expression of CXCR4 by flow cytometry (Fig 1B). As expected, the pro-B cell line, Reh, and the pre-B cell line, Nalm-6, also expressed high levels of CXCR4 (Fig 1B).

We found that CLL B cells from each of 12 patients expressed high levels of CXCR4. The T cells in the samples expressed lower levels of CXCR4 than CLL B cells (Fig 2A). The mean fluorescence intensity ratio of CLL cells from 12 different patients was 274 ± 68 (mean ± SD, n = 12), whereas it was 122 ± 34 for the T cells of the same patients (Fig 2A).

SDF-1α induces dose-dependent CXCR4 receptor endocytosis. Receptors internalization by endocytosis is characteristic for chemokine receptors and may allow for continuous sampling of chemoattractants, permitting the cells to follow a chemotactic gradient. Figure 2B shows the mean fluorescence of B-CLL cells stained with anti-CXCR4 MoAbs after incubation with varying concentrations of SDF-1α or medium alone. We found that the amount of SDF-1α required to induce maximum downmodulation on CLL B cells was equal to 1,000 ng/mL, or 125 nmol/L. This is similar to the amount required for optimal downmodulation of CXCR4 on T cells of the same patient (Fig 2B) or Nalm-6 (data not shown). In addition, we...
observed a partial CXCR4 downmodulation on CLL B cells (Fig 2B) or Nalm-6 in response to SDF-1α at concentrations as low as 1 ng/mL. This was lower than the concentration of SDF-1α that was required to induce detectable CXCR4 downmodulation on T cells of the same CLL patients and might indicate high sensitivity of CXCR4 on CLL B cells to SDF-1.

SDF-1α induces calcium mobilization in CLL B cells. Binding of chemokines to their receptors causes a characteristic increase in cytosolic calcium. This is one of the earliest biochemical events that occur in response to chemokines. To examine intracellular calcium flux, we labeled CLL cells or the B-cell lines, Nalm-6 and Reh, with indo-1–AM before adding SDF-1α to 100 ng/mL. Evaluation of the fluorescence of stimulated cells showed that both CLL B cells and normal B cells mobilize Ca^{2+} in response to SDF-1α. Compared with the immature B-cell lines, Nalm-6 or Reh (Fig 3A and B), CLL cells (n = 6) had a prolonged elevation in intracellular free Ca^{2+} after stimulation with SDF-1α.

SDF-1α induces actin polymerization in CLL B cells. Reorganization of the actin cytoskeleton is an early event in the migratory response to chemokines. To evaluate the ability of SDF-1α to induce changes in the actin cytoskeleton of CLL B cells, we examined for changes in filamentous actin (F-actin) of CLL cells in response to 100 ng/mL SDF-1α. We detected a significant, transient increase in F-actin within 15 seconds after exposure of the cells to the chemokine, followed by a subsequent depolymerization, as shown in Fig 3C. Actin polymerization after SDF-1α stimulation was inhibited by preincubation of CLL B cells with pertussis toxin (Fig 3C), indicating that this response is mediated through pertussis toxin-sensitive G protein–linked receptors.

Chemotaxis of CLL cells in response to SDF-1α. We performed a chemotaxis assay in which B-CLL cells were evaluated for their ability to migrate through 5-µm pores of bare polycarbonate filters. This assay allowed us to determine the absolute number, as well as the phenotype of the transmigrated cells. Figure 4A shows the chemotaxis response of CLL B cells to various concentrations of synthetic SDF-1α, as determined by immunophenotyping of input and transmigrated cells. The average proportion of CLL B cells that migrated to chambers with the optimal concentration of SDF-1α (100 ng/mL) was 16% ± 9% of input cells (mean ± SD, n = 16 patients). In contrast, the proportion of input cells that migrated to control chambers without SDF-1α was 1% ± 2% (Fig 4A). The response to SDF-1α had a biphasic curve that is characteristic for chemoattractant-induced chemotaxis (Fig 4C). The pro-B cell line, Reh, and the pre-B cell line, Nalm-6, also migrated to chambers containing SDF-1α, as described earlier. The maximum migration response also was noted to chambers containing 100 ng/mL SDF-1α.

The chemotaxis of CLL cells was significantly inhibited by preincubation of the input cells with the anti-CXCR4 MoAb 12G5, indicating that a direct interaction between SDF-1α and CXCR4 was necessary for chemotaxis (Fig 4B). In contrast, preincubation with a control MoAb against the chemokine receptor, CCR3, had no significant effect.

Chemotaxis of CLL B cells to SDF-1α was completely blocked by pertussis toxin (Fig 4C), indicating that this activity was dependent on signaling through a Gi protein(s). Furthermore, pretreatment with Wortmannin, a selective inhibitor of PI-3 kinase, partially inhibited SDF-1α–induced migration of CLL B cells (Fig 4D). The phenotype of the migrated cells indicated that the proportion of CLL B cells and T cells did not differ between samples pretreated with Wortmannin or controls.
indicating that Wortmannin inhibited the migration of both cell types.

M2-10B4 stromal cells express SDF-1 mRNA and secrete bioactive SDF-1. Using SDF-1β–specific PCR primers, we amplified a PCR product of the expected size (296 bp) from M2-10B4 cDNA and a sequenced plasmid containing the murine SDF-1β cDNA served as a positive control, demonstrating SDF-1 expression by the stromal cell line (Fig 5A). Conditioned medium from this cell line induced chemotaxis of Reh cells in a dose-dependent fashion, and this migration was blocked by preincubation of the cells with anti-CXCR4 MoAbs (Fig 5B). Moreover, preincubation with M2-10B4–conditioned medium induced a dose-dependent downmodulation of CXCR4 receptors on Reh cells, compared with cells preincubated in medium alone (data not shown). These observations indicated that the M2-10B4 line expresses and secretes SDF-1.

CLL B cells migrate beneath heterologous MSC (Pseudoemperipolesis). Coculture of CLL cells with the murine-marrow-stroma cell-line, M2-10B4, results in spontaneous migration of CLL cells into the stromal cell layer. This in vitro phenomenon termed pseudoemperipolesis is characterized by the dark appearance of cells that have migrated into the same focal plane as the stromal cells, whereas the more superficial, nonmigrated cells remain refractile (Fig 6).30 Time-course experiments showed that pseudoemperipolesis of CLL cells mostly occurred within the first 2 hours of coculture (Fig 7B). Titration of the input CLL cell numbers showed that concentrations above 1×10^7 per 24 well plate did not significantly increase the number of migrated cells (Fig 7C). A 2-hour assay with 1×10^7 input cells was found to be the optimal condition for this assay and hence was used in subsequent inhibition studies. Under these conditions, an average of 7.4% ± 3.7% (mean ± SD) of input CLL cells from 6 different patients migrated into the stromal layer. For comparison, we assessed the migration of Nalm-6 cells and found that 6.9% ± 0.5% (mean ± SE of duplicate tests) of the input cells migrated into the stromal layer under the same experimental conditions.

Pseudoemperipolesis of CLL B cells is associated with strong CXCR4 downmodulation and increased expression of CD49d. CLL B cells that had migrated into the stromal cell layer and input CLL cells were analyzed for surface marker expression by co-staining with FITC-labeled anti-CD19 MoAb and PE-conjugated MoAbs to the epitopes of interest. First, we examined for CD19 and CD3 expression on the migrated lymphocytes. Similar to the input CLL cells, the CD19-positive CLL B cells were the predominant population of transmigrated cells (82% ± 14.7% of the migrated lymphocytes, n = 6). Comparing the mean fluorescence intensity ratios (MFIR ± SD), we noted a significantly lower CXCR4 expression (CXCR4 MFIR, 50 ± 21 v 423 ± 184, n = 4; P < .05) and higher CD49d expression (CD49d MFIR, 13 ± 2 v 7 ± 2; n = 4, P < .05) on the transmigrated CLL B cells than on the input CLL B cells (Fig 8A), whereas no difference was observed for the expres-
expression of CD49e and CD54 (CD49e MFIR, 6 ± 5 v 6 ± 5; n = 4; CD54 MFIR, 24 ± 11 v 25 ± 9; n = 4).

Role of SDF-1 in pseudoemperipolesis of CLL B cells. To establish the role of SDF-1 in the migration of CLL cells into the stromal layer, we used inhibitors that specifically or nonspecifically interfered with the interaction of SDF-1 or CXCR4 on CLL cells. Pertussis toxin was the strongest inhibitor of CLL cell pseudoemperipolesis: only 14% ± 6% (mean ± SD; n = 6) cells compared with untreated control samples (100%) had migrated after 2 hours. Significant inhibition was also observed after SDF-1α pretreatment and addition to the coculture (35% ± 19%; n = 6), and anti-CXCR4 MoAb preincubation of CLL cells (58% ± 16%; n = 6; Fig 6B).

**DISCUSSION**

In this study, we investigated the expression and function of the chemokine receptor, CXCR4, on B cells from patients with CLL and characterized its role in heterotypic adherence to marrow stromal cells. First, we stimulated CLL B cells with synthetic SDF-1α and detected responses that are characteristic for the activation of leukocytes by chemoattractants (chemokine receptor endocytosis, calcium mobilization, actin polymerization). Moreover, CLL B cells migrated in response to SDF-1α, showing a biphasic dose response curve that is characteristic for chemokine-induced migration. The chemotaxis of CLL B cells toward SDF-1α was mediated by signaling through the CXCR4 receptor, as demonstrated by our ability to inhibit such migration with anti-CXCR4 MoAb 12G5. Preincubation with this MoAb significantly reduced chemotaxis of CLL B cells in response to SDF-1α (72% inhibition with 30 µg/mL anti-CXCR4 MoAb; Fig 4B). The failure to achieve 100% inhibition under these conditions has been noted earlier, and may reflect the competition of relatively high concentrations of chemokine (eg, 100 ng/mL) with anti-CXCR4 MoAbs during a 2-hour assay. Internalization and recycling of CXCR4 receptors after MoAb binding or partial dissociation of this MoAb at the physiologic temperatures of the chemotaxis assay may play a role in this context.

We also found that the migration of CLL B cells could be inhibited by pretreatment of the CLL cells with pertussis toxin or Wortmannin, indicating that SDF-1α signaling for migration of CLL B cells is linked to a CXCR4 coupled Gα subunit of a
heterotrimeric guanosine triphosphate (GTP)-binding protein and activation of PI3-kinase, respectively.

In hematopoietic cells, SDF-1 treatment also can activate p44/42 mitogen-activated protein kinase (Erk1 and Erk2) through CXCR4. This downstream signaling pathway may play a role in SDF-1–induced transcriptional activation. In addition, there are reports that the specific p44/42 mitogen activated protein kinase (MAPK) inhibitor, PD98059, could inhibit chemotaxis of eosinophils induced by eotaxin or of neutrophils induced by N-formyl peptide, C5a, or interleukin-8, suggesting that the Erk-pathway also may be involved in signaling for chemotaxis. However, this remains controversial, as other reports indicate that PD98059 could not inhibit neutrophil-chemotaxis induced by f-Met-Leu-Phe (fMLP) or interleukin-8 or the platelet-derived growth factor-induced chemotaxis of fibroblasts. Consistent with such reports are our preliminary studies in which we did not observe significant inhibition of SDF-1–induced chemotaxis with 50 µmol/L PD98059 for CLL cells from any 1 of 5 different donors (data not shown). As such, it appears that the p44/42 MAPK pathway may not be necessary for SDF-1–induced CLL cell migration.

Having established that CLL B cells express functional CXCR4 chemokine receptors, we went on to investigate the importance of this receptor for interactions with marrow stromal cells, which are a major source of the chemokine SDF-1 in vivo. We found that CLL B cells can spontaneously migrate beneath marrow stromal cells within 2 hours. This striking in vitro phenomenon termed pseudoemperipolesis was demonstrated by phase contrast microscopy by the dark appearance of lymphocytes that migrated into the same focal plane as the stromal cells. The term pseudoemperipolesis is used to describe symbiotic complexes of leukemia cells with their stromal cell component in vitro. In this context, stromal cells also are referred to as “nurse-like cells.” During this cell interaction, leukemia cells migrate beneath the adherent cells or are trapped by membrane projections, but do not become internalized. It is used to distinguish this type of cell interaction from “true” emperipolesis, the internalization of lymphocytes by sessile cells, first described in situ for thymocytes internalized by thymic stromal cells (thymic nurse cells).

Earlier studies on the molecular mechanism of heterotypic adherence between marrow stromal cells and B cells demonstrated that this is a biphasic process, characterized by an early phase of adherence (≤15 minutes). This process partly depends on the interaction between very late antigen-4 (VLA-4; or CD49d) on B lymphocytes with vascular cell adhesion molecule-1 (VCAM-1; or CD106), expressed on stromal cells. The higher expression of CD49d (VLA-4) integrins on migrated CLL B cells compared with input CLL B cells can either be interpreted as an enrichment of CLL B cells expressing higher levels of CD49d, allowing those to enter the stromal cell layer, or could be explained as an induction of CD49d expression.
expression by signals delivered during the migration process. In either case, this observation suggests that CLL B cells interact with VCAM-1 or fibronectin on marrow stromal cells.

The late phase of heterotypic adherence ($\geq$30 minutes), associated with pseudoemperipolesis, does not depend on CD49d/VLA-4 engagement. While the early phase of adherence may allow for the initial homing to the marrow, the late phase, where leukemia cells come into closer contact with stromal cells, may confine malignant B cells within the bone marrow, as suggested by Patrick et al.

In this study, we demonstrated that the chemokine SDF-1 plays a critical role for pseudoemperipolesis, the late phase of heterotypic adherence of CLL B cells to marrow stromal cells according to the above-mentioned model. The almost complete inhibition of migration into the stromal cell layer by pertussis toxin demonstrates that signaling through a Gi protein coupled receptor is required for this migration. The pretreatment of CLL B cells with SDF-1 and the addition of this chemokine to the coculture significantly reduced the pseudoemperipolesis by about 65% compared with nontreated controls. This condition uses 2 antagonizing mechanisms that can interfere with SDF-1–induced migration of CLL B cells into the stromal layer. First, the pretreatment of the CLL cells with this chemokine induces a downmodulation of the CXCR4 receptor on CLL B cells to levels that are $\leq$10% of nontreated cells, as demonstrated in the receptor endocytosis assay (Fig 2B). Second, by adding these cells in SDF-1 containing medium to the coculture, the exogenous SDF-1 can interfere with a SDF-1 gradient established by SDF-1 secreting stromal cells that otherwise may allow for the directional migration into the stromal cell layer. Direct evidence for the importance on SDF-1 for this migration is provided by significantly blocking pseudoemperipolesis with an anti-CXCR4 MoAb, whereas a control antibody was without any effect (Fig 8B). Finally, the strong downmodulation of CXCR4 on CLL B cells that had migrated into the stromal cell layer provides further evidence that SDF-1 contributes to this migration process. From these observations, we propose that heterotypic adhesion between CLL B cells and marrow stromal cells is a multistep process comparable to transendothelial migration, involving the sequential engagement of adhesion molecules and activation through chemokine receptors, in particular CD49d/VLA-4 and CXCR4, respectively.

Earlier studies by Lagneaux et al and others demonstrated that CLL B cells could adhere to human marrow stromal cells. They noted that this adhesion was partly mediated through $\beta_1$ and $\beta_2$ integrins, and direct contact with stromal cells prevented spontaneous or steroid-induced apoptosis of CLL B cells. In contrast, only very few normal CD5+ B cells adhered to marrow stromal cells, and those were not protected from spontaneous apoptosis. It has therefore been proposed, that the marrow microenvironment, in particular marrow stromal cells, provide factors that allow for the accumulation of CLL B cells and make them more resistant to chemotherapy.

Because SDF-1 induces chemotaxis of CLL B cells and is critical for the spontaneous migration of leukemic CLL B cells beneath marrow stromal cells, we propose that this chemokine
allows for the infiltration of the marrow by leukemic CLL cells. In addition, SDF-1 may not only direct, but also confine CLL B cells within the medullary cavity, similar to the recently demonstrated mechanism of progenitor B-cell retention in the marrow by SDF-1.\(^1\) Attraction through the CXCR4 chemokine receptor therefore provides a new mechanism to explain how neoplastic B cells can access limited supportive microenvironmental niches in the marrow, which usually are restricted to progenitor cells.

Further studies will have to define whether inhibiting the heterotypic adhesion of B-CLL cells to marrow stromal cells, for example by interfering with CXCR4-receptor signaling in CLL B cells, could modify the growth or survival of CLL B cells. Therefore, future studies on the role of SDF-1 in the interaction of CLL B cells with marrow stromal cells may lead to new therapeutic strategies for patients with this disease.

ACKNOWLEDGMENT

The authors are grateful to Drs L.Z. Rassenti and K. Kato for providing B-CLL cDNA samples and to T.A. Johnson for excellent technical assistance. We thank Dr I. Clark-Lewis for the generous gift of SDF-1α, Dr I.U. Schraufstatter for providing the p44/42 MAPK inhibitor PD98059, and Dr N.J. Zvaifler for suggestions and the critical evaluation of the manuscript.
