Response to hypoxia involves transforming growth factor-β2 and Smad proteins in human endothelial cells

Hasan O. Akman, Hong Zhang, M. A. Q. Siddiqui, William Solomon, Eric L. P. Smith, and Olcay A. Batuman

Oxygen deprivation (hypoxia) is a consistent component of ischemia that induces an inflammatory and prothrombotic response in the endothelium. In this report, it is demonstrated that exposure of endothelial cells to hypoxia (1% O2) increases messenger RNA and protein levels of transforming growth factor-β2 (TGF-β2), a cytokine with potent regulatory effects on vascular inflammatory responses. Messenger RNA levels of the TGF-β2 type II membrane receptor, which is a serine threonine kinase, also increased. The stimulatory effect of hypoxia was found to occur at the level of transcription of the TGF-β2 gene and involves Smad proteins, a class of intracellular signaling proteins that mediates the downstream effects of TGF-β receptors. Transient transfection studies showed that the region spanning -77 and -40 base pairs within the TGF-β2 promoter (harboring a Smad-binding “CAGA box”) is activated in hypoxic cells compared with nonhypoxic controls (P < .01). Hypoxia also stimulated transcription from another promoter, 3TP-Lux, a reporter construct responsive to Smads and TGF-β. In addition, specific binding to a Smad-binding oligonucleotide was observed with nuclear extracts from hypoxic endothelial cells but not from nonhypoxic cells. It is concluded that Smad proteins, which can regulate endothelial responses to mechanical and inflammatory stress, also may play an important role in vascular responses to hypoxia and ischemia. (Blood. 2001;98:3324-3331)

Introduction

One of the earliest responses of endothelium to hypoxia is inflammation, and the balance between positive and negative regulators of this inflammatory response is a determinant of endothelial adaptation to hypoxia. Proinflammatory endothelial responses induced by hypoxia involve production of cytokines, chemokines,1,3 tissue factor,4 and plasminogen activator inhibitor-1 (PAI-1).5 Recent studies indicate that activation of the transcription factor early growth response-1 (Egr-1) by hypoxia is responsible for the procoagulant profile and vascular remodeling that ultimately result in the tissue damage associated with ischemia.4 Adaptive responses to hypoxia are also regulated at a transcriptional level, which is best exemplified by activation of the transacting protein hypoxia-inducible factor-1 (HIF-1), which stimulates differential expression of specific genes and results in increases in glucose uptake, glycolytic enzyme production, and angiogenesis.6,7

The transforming growth factor-β (TGF-β) family of growth factors has an especially critical role in modulation of vascular inflammatory responses and remodeling.8,10 and up-regulation of TGF-β production is an invariant response to vascular injury, indicating that regulation of gene expression of the TGF-β proteins by quiescent and injured endothelium is likely to be a critical factor affecting the course of vascular inflammation. This hypothesis is supported by demonstration of defective vasclogenesis and increased and ultimately lethal vascular inflammation in mice null for TGF-βs,11,12 their membrane receptors,13,14 or their downstream substrates, the Smad proteins.15,16

Three mammalian isoforms of TGF-β (TGF-β1, TGF-β2, TGF-β3)11,12,17,18 are secreted by endothelial cells in a latent form in which latency-associated peptide (LAP) and its 25 kd carboxy-terminal dimer, which is the mature TGF-β1,19,20 remain noncovalently bound. In vivo release of the mature dimer from LAP occurs via its degradation or conformational change19,21 and allows binding of the mature (bioactive) peptide to its specific membrane receptors TGF-βRI, TGF-βRII, and TGF-βRIII, of which types I and II are serine threonine kinases.22,24 Binding of the 25 kd TGF-β dimer to the high-affinity type II receptor results in recruitment and activation of the type I receptor by phosphorylation at its cytoplasmic domain by the type II receptor kinase. Activated TGF-βRI phosphorlylates intracellular Smad proteins, which propagate downstream signals of TGF-βs.25 Phosphorylation of Smad2 and Smad3 (receptor-activated Smads) causes their dissociation from TGF-βRI and stimulates their assembly with Smad4 (co-Smad)22,26; this complex then translocates and accumulates in the nucleus. Heterodimeric Smad complexes can bind DNA in either orientation of the 5′-CAGA′- consensus sequence (Smad-binding element [SBE]27-29) and can directly regulate transcription by recruiting coactivators or inhibitors of transcription.30

Recent studies of human endothelial cells and in vivo animal studies have shown that Smad proteins regulate endothelial responses to mechanical stress such as shear31,32 and to inflammatory stress such as exposure to bacterial lipopolysaccharide.33 It seemed reasonable, therefore, to test the hypothesis that TGF-βs and their downstream Smad signaling pathway can be activated by hypoxic...
stress in vascular endothelium in humans. In this report, we show that hypoxia selectively up-regulates the TGF-β2 isoform by as much as 20-fold in endothelial cells in a time-dependent fashion. Furthermore, we show for the first time that hypoxia activates Smad-mediated gene transcription and Smad-DNA association in human endothelial cells. These data indicate a new function for Smads in endothelial cells as one of the signaling pathways activated by hypoxia, one that is capable of modulating inflammatory consequences of ischemia.

Materials and methods

Cell cultures

Primary human umbilical vein endothelial cells (HUVECs) were isolated and propagated from pooled primary cultures of umbilical veins by digestion with collagenase type II and were maintained as described by Gimbrone. 34 Briefly, HUVECs were grown on gelatin (2%)-coated tissue culture flasks (Costar, Cambridge, MA) in endothelial cell growth medium that consisted of medium 199 (Gibco, Grand Island, NY) supplemented with endothelial cell growth supplement (50 μg/mL; Calbiochem, San Diego, CA), 20% fetal bovine serum, antibiotics (100 U/mL penicillin G, 100 μg/mL streptomycin), and heparin (50 μg/mL; porcine intestinal; Sigma, St. Louis, MO). Cells were passaged by trypsin–ethylene diaminetetraacetic acid (EDTA) treatment, split 1:4, fed every 1 to 3 days, and used at second or third passage, when nearly confluent (70%). Cytoplasmic von Willebrand factor by immunocytochemistry and nonoverlapping cobblestone morphology verified endothelial cells. For exposure to hypoxia, cells were incubated under an atmosphere of 1% O2, 5% CO2, and 94% N2 at 37°C in a NAPCO 7301 incubator (Precision Scientific, Chicago, IL). Previous experiments in our laboratory have shown that during exposure to hypoxia, the pH of the medium remains unchanged, pH7; in the medium is 10 to 16 mm Hg, and viability is more than 95% as measured by trypan blue dye exclusion and determination of release of lactate dehydrogenase. Experiments were performed in parallel on normoxic and hypoxic cells that were exposed for the times indicated to hypoxia or recombinant TGF-β2 (R&D Systems, Minneapolis, MN). HUVEC viability assessed after each treatment was consistently more than 95%. HUVECs were cultured in either normoxic or hypoxic culture conditions. Briefly, a suspension of 6 × 104 cells was cultured in either normoxic or hypoxic culture conditions. Each well was measured as relative light units (RLUs; model TD-20/20 luminometer, Promega), which were converted to TGF-β activity (picomoles) using the TGF-β2 standard curve.59 Total protein content of supernatants was quantitated using Bio-Rad protein assay reagent (Bio-Rad, Hercules, CA), 36 and TGF-β2 levels obtained by the luciferase assay from each well were normalized to protein. Mean RLUs from triplicate wells (which were within 5%–7% of one another) were converted to picomoles of TGF-β2. This assay is sensitive to all 3 isoforms of TGF-β; therefore, to specifically quantify total TGF-β2 in hypoxic and nonhypoxic supernatants, aliquots of the identical supernatants used in MLEC assay were acid-activated and subjected to enzyme-linked immunosorbent assay (ELISA) (Quantikine, R&D Systems) as previously described. 37 Results (not shown) confirmed that TGF-β2 levels were increased by 2-fold in hypoxic supernatants. Because measurement of bioactive TGF-βs by ELISA is not yet reliably accomplished by existing commercial kits, this assay can only confirm the increase in total TGF-β2 determined by the MLEC assay.

Nuclear run-on assay for TGF-β2

The rate of transcription of TGF-β2 in HUVECs was determined as described by Greenberg and Ziff 38 in nuclei prepared from HUVECs cultured in either normoxic or hypoxic culture conditions. Briefly, a suspension of 6 × 104 nuclei in 200 μL glycerol (40%) in 50 mM Tris-HCl buffer (pH 8.3, with 5 mM MgCl2 and 0.1 mM EDTA) was mixed with 2 × reaction buffer (10 mM Tris-HCl [pH 8]; 5 mM MgCl2; 0.3 M KCl; 5 mM dithiothreitol; 1 mM each ATP, CTP, GTP, and 100 μCI [3.7 × 108 Bq] [32P]UTP [1 × 106 Bq; 3000 Ci/mM; PerkinElmer Life Sciences, Boston, MA]). After incubation for 30 minutes at 30°C, [32P]UTP-labeled RNA was treated twice with phenol/chloroform/isooamyl alcohol (25:24:1) and 50 μg transfer RNA, and 10% trichloroacetic acid (TCA) were added. The mixture was filtered through a 0.45-μm Millipore filter (Millipore, Bedford, MA). Nuclear RNA from the filter was released by treatment with 20 μM HEPES buffer (pH 7.5, with 5 mM MgCl2 and 1 mM CaCl2) and deoxyribonuclease for 30 minutes at 37°C, addition of 45 μL of 0.5 M EDTA and 68 μL of 20% SDS, and incubation at 65°C for 10 minutes. Nuclear RNA was digested with proteinase K, extracted with phenol/chloroform/isooamyl alcohol, and ethanol-precipitated at −20°C overnight.
TGF-β2, Glut-1, and GAPDH complementary DNA probes have been described.\(^{39,41}\) RNA was hybridized for 36 hours at 65°C to linearized plasmid DNA (TGF-β2, Glut-1, GAPDH) immobilized on nitrocellulose membranes.\(^{41}\) Filters were washed in SSC (2×) at 65°C 3 times for 30 minutes each, incubated at 37°C with 80 μg ribonuclease A, washed again, air dried, and exposed to Dupont reflection film (DuPont Pharmaceuticals, Wilmington, DE), with an intensifying screen, at −80°C, and also by exposure to PhosphorImager. For quantification of TGF-β2-transcription and determination of the fold increase in transcript levels in hypoxic HUVECs compared with control, the TGF-β2/GAPDH signal ratio from hypoxic HUVECs was divided by the TGF-β2/GAPDH signal obtained from normoxic HUVECs.

Plasmid constructs

Plasmid constructs containing deletion mutants of the human TGF-β2 gene promoter linked to a chloramphenicol acetyl transferase (CAT) gene were generously donated by Dr S.-I. Kim.\(^{42}\) TGF-β2/CAT constructs pB2-778, pB2-257, and pB2-40 were generated by polymerase chain reaction using genomic DNA containing the 5′-flanking DNA and the first exon of the TGF-β2 gene as template with different 5′-specific oligonucleotide primers, spanning from −778 to −40, and a common 3′-specific oligonucleotide primer at +63 relative to the transcription initiation site; amplified DNAs were cloned into the promoterless pGEM4/SV/CAT vector as described.\(^{32}\) The p3TP-Lux construct (a generous gift from Dr Joan Massague, Memorial Sloan-Kettering Cancer Center, New York, NY) is a well described and widely used artificial promoter construct that was designed to have maximal responsiveness to TGF-β described and widely used artificial promoter construct that was designed to have maximal responsiveness to TGF-β.

Transfection of recombinant plasmids and reporter gene assays

For transient transfections, plasmids containing 5′ TGF-β2 promoter sequences and p3TP-Lux containing the luciferase reporter gene, with determination of the fold increase in transcript levels in hypoxic HUVECs, was divided by the TGF-β2/GAPDH signal obtained from normoxic HUVECs.

Effect of hypoxia on TGF-β mRNA and protein levels in HUVECs

As shown in Figure 1A, in nonhypoxic HUVECs, TGF-β1 mRNA levels were greater than mRNA levels of TGF-β2 or TGF-β3. The strongest effect of hypoxia was on TGF-β2 mRNA levels, which increased by 4-fold after 4 hours of exposure to hypoxia compared with untreated HUVECs, followed by 10-fold and 25-fold increases at 24 hours and 48 hours, respectively (Figure 1A,B). At each time point, mRNA from nonhypoxic control HUVECs was also analyzed, and the TGF-β mRNA profile from these cultures remained unchanged (data not shown). Viability of endothelial cells at 24 hours and 48 hours, as disclosed by trypan blue and lactate dehydrogenase release, was more than 95%. A strong effect of hypoxia was observed on TGF-β bioactivation (Figure 1C). The level of bioactive TGF-β, which was assayed in supernatants prior to activation of latent TGF-β, was 12 times higher in supernatants from hypoxic HUVECs compared with normoxic control supernatants. Thus, 64% of TGF-β in supernatants from hypoxic HUVECs was bioactive, while only 14% of total TGF-β was bioactive in the nonhypoxic supernatants\(^{30}\) (Figure 1C). The level of total TGF-β activity, CAT/β-gal/protein or RLU/β-gal/protein ratios for hypoxic and nonhypoxic transfectants were compared to determine the fold induction by hypoxia. The displayed error bars in Figures 5 and 6, which are each representative of at least 3 independent experiments, represent ± 1 SD of the mean.
(which is determined after activation of latent TGF-β) produced by HUVECs after 48 hours of exposure to hypoxia was increased by 2.6-fold compared with nonhypoxic cells (P < .05) both by the MLEC assay (Figure 1C) and by an ELISA that specifically measures TGF-β (data not shown). As seen in Figure 2, nonhypoxic HUVECs have readily discernable levels of both TGF-βRI and TGF-βRII mRNA. While hypoxia did not alter mRNA levels of TGF-βRII, there was a modest but consistent 1.8- to 2.5-fold increase in levels of the serine threonine kinase TGF-βRII in hypoxic HUVECs (P < .05) after correction for L32 expression (data not shown), suggesting that in these cells hypoxia could activate TGF-β signaling as well. Up-regulation of vascular endothelial growth factor in this experiment (Figure 2) confirms hypoxic conditions.47

Level of hypoxia-induced TGF-β2 gene expression in HUVECs

As suggested by Semenza,6,48 several adaptive responses to hypoxia involve changes in gene expression that occur at the level of transcription. To examine whether the hypoxia-induced stimulation of TGF-β2 mRNA resulted from an up-regulation of its transcriptional activation, we used in vitro transcription assays performed with nuclei isolated from HUVECs exposed to 20% or 1% O2 for 24 hours. The results from 1 of 2 experiments that yielded identical results are shown in Figure 3 and demonstrate that hypoxia increased transcription of TGF-β2 by 15-fold after normalization to GAPDH (data not shown). Similarly, transcription of the
hypoxygen-responsive glucose transporter-1 (Glut-1) gene was also increased under hypoxygen culture conditions, whereas transcription of the housekeeping gene GAPDH was largely unchanged. Furthermore, treatment with α-amanitin to block type II RNA polymerase activity exhibited very similar decay curves in hypoxygen and normoxic HUVECs (Figure 4B), indicating that hypoxia’s effect on TGF-β2 gene expression occurred largely at the transcriptional level.

To further study hypoxygen-induced TGF-β2 transcriptional activation, we performed transient transfection assays using CAT reporter constructs containing the 5’ TGF-β2 promoter sequences. First, activity of the CAT reporter construct pB2-778, which contains cis-acting elements (Figure 5A) that regulate transcription of the 5.8 kilobase TGF-β2 transcript, was determined. As shown in Figure 5B, activity of this construct was increased by 3-fold in response to hypoxygen, and further studies using deletion mutants of this construct showed that the promoter sequence within pB2-77 is necessary and sufficient to mediate the 4.8 ± 1.2-fold increase in CAT activity obtained in hypoxygen cells compared with normohypoxic controls. A hypoxygen-induced 4.8-fold increase in transcription from the TGF-β2 promoter region between −77 and +63 bp compared with normohypoxic controls (P < .001) paralleled the increase seen in the mRNA levels after 24 hours of exposure to hypoxygen, suggesting that the stimulatory mechanism involves changes associated with transcriptional events.

TGF-β3s are known to be regulated by cis-acting Smad sites. Because the TGF-β promoter region within the hypoxygen-responsive construct pB2-77 harbored a Smad-binding site (Figure 5A) and because endogenous Smad activity is known to be boosted by Smad overexpression,25,50 we tested the hypoxygen response of the −77 to +63 bp CAT construct after Smad3 and Smad4 overexpression in HUVECs. Results show that overexpression of Smad3 and Smad4 resulted in a further 1.8-fold increase in construct pB2-77 activity in hypoxygen HUVECs (Figure 5B) compared with nonhypoxygen controls (P < .01). Baseline expression of constructs under normoxic conditions and response of pB2-778 or pB2-40 to overexpression of Smads did not have a significant effect on their CAT activities (data not shown).

We next examined whether hypoxygen stimulated activity of another promoter construct with known responsiveness to activation by Smad proteins using a well described and widely used artificial promoter construct, plasmid p3TP-Lux (Figure 6A), which is responsive to TGF-β as well as to Smad3 and Smad4 cooverexpression even in the absence of ligand.23 As seen in Figure 6B, hypoxygen increased the luciferase activity of p3TP-Lux by 3.5-fold in HUVECs and by 10-fold in HepG2 cells, which are easier to transfect than HUVECs and thus are less subject to artifacts resulting from low transfection efficiencies. These results indicate that endogenous Smads are activated by hypoxygen in both cell types. As expected, addition of TGF-β2 to HUVECs or HepG2 cells increased luciferase activity of 3TP-Lux (Figure 6A,B). To further determine the role of Smad proteins on hypoxygen-induced activity of p3TP-Lux, we measured its response to hypoxygen after transfection into the Smad4-null, epithelial breast adenocarcinoma cell line MDA-MB-468. In contrast to results obtained in HUVECs and HepG2, hypoxygen-driven luciferase activity of p3TP-Lux was minimal in MDA-MB-468 (Figure 6C). When these cells were transiently transfected to express Smad4, there was a 4-fold increase in the p3TP-Lux activity, indicating that Smad4 is necessary for hypoxygen-induced transcription in this cell line. Hypoxia also modulates expression of genes regulated by the transcription factor AP-1,31-33 and Smad3 and Smad4 potentiate transcription from AP-1,20 suggesting that Smad and AP-1 responses may both contribute to hypoxygen-induced 3TP-Lux activity.

**Nuclear extract binding to the Smad consensus sequence**

Smad binding to DNA was studied by comparing gel retardation patterns of nuclear proteins from HUVECs exposed to hypoxygen, normoxia, or TGF-β to DNA sequences that are specific for binding Smad proteins. As the probe in the electrophoretic gel mobility shift assay, we used the well-described oligonucleotide SBE which, as shown by x-ray crystallography, can associate with Smad3 or Smad4 or both of its palindromic Smad-binding sequences.29 As seen in Figure 7A, after exposure to hypoxygen a discrete gel-shifted band was observed that was absent from control nonhypoxygen nuclear extracts. This band was identical in position to the one observed with nuclear extracts of TGF-β2-treated HUVECs and raised the possibility that hypoxygen induced Smad binding to DNA. Binding to the SBE by nuclear extracts stimulated by hypoxygen or by TGF-β2 was competed by an unlabeled 37 bp oligonucleotide corresponding to the hypoxygen-responsive TGF-β2 promoter sequences between −77 and −40 bp and containing a Smad-binding site.
However, unlabeled oligonucleotide corresponding to the HIF-1 binding site of the erythropoietin promoter did not compete binding of hypoxic nuclear extracts to the SBE. Results suggest that the shared Smad-binding site between the SBE and the hypoxia-responsive TGF-β2 promoter between −77 and −40 bp can bind nuclear proteins in hypoxic but not normoxic cells and that binding is independent of HIF-1.

To identify the transcription factors participating in the DNA association in nuclear extracts from TGF-β2 and hypoxia-treated HUVECs, supershift assays were performed with antibodies specific for Smad2, Smad3, and Smad4 and also with preimmune sera (not shown). As shown in Figure 7B, antibody to Smad3 and Smad4 supershifted the bands seen with nuclear extracts from TGF-β2– and hypoxia-treated HUVECs, while preimmune sera did not induce a supershift (data not shown). Furthermore, antibody to Smad2 did not induce a supershift but decreased the intensity of the specific association of hypoxia- and TGF-β–treated nuclear extracts with the SBE, indicating that Smad2 function may also be activated by hypoxia in endothelial cells. These results suggest that hypoxia induces Smad-DNA association similar to that induced by TGF-β2 and support the thesis that hypoxia results in Smad3 and Smad4 activation.

**Discussion**

In this report, we show that hypoxia increases TGF-β2 production and its bioactivation in human endothelial cells; furthermore, hypoxia effectively up-regulates TGF-β2 mRNA levels. This effect occurs at the transcriptional level, as evidenced by nuclear run-on analysis and reporter gene experiments using the TGF-β2 promoter, and is at least partly mediated by Smad proteins, because their overexpression further stimulates TGF-β2 promoter activation by hypoxia. It is possible that an autocrine mechanism in which bioactivation of TGF-β by hypoxia results in TGF-β–mediated activation of Smads and results in TGF-β2 transcription; alternatively, Smad activation occurs by a pathway that is independent of TGF-βR. Activation of Smads by receptor and intracellular kinases other than those within TGF-β pathway have been described. For example, the intracellular kinase mitogen-activated protein kinase-1, an upstream activator of the stress-activated protein kinase/c-Jun N-terminal kinase, can activate Smads in endothelial cells. In view of the fact that hypoxia activates intracellular kinases p38, p38 mitogen-activated protein kinase, and stress-activated protein kinase/c-Jun N-terminal kinase, it is likely that Smad protein signaling in hypoxic endothelial cells is regulated by multiple mechanisms. Responses to hypoxia of negative regulators of the Smad pathway—for example, Smad7, which can regulate endothelial responses to inflammation and shear—are unknown at this time.

Our results show that the HIF-1–binding oligonucleotide cannot compete association of hypoxic nuclear extracts with SBE. In addition, exposure to 200 μM hydrogen peroxide, which depletes HIF-1α accumulation in hypoxic cells and inhibits its ability to bind DNA, is associated with a 4-fold increase in TGF-β2 mRNA levels in hypoxic HUVECs and HepG2 (data not shown). Existing reports indicate a possible negative regulation of the Smad pathway by HIF-1, such as reduction of TGF-β1 gene expression in fetal skin by HIF-1 and inhibition of HIF-1 causing TGF-β3 gene expression and suppression of its downstream effects on trophoblasts. The potential interaction of Smad and HIF pathways in regulating gene expression in hypoxic endothelium is of interest.

**Figure 6.** Hypoxia stimulates transcription from 3TP-Lux in HUVECs. (A) Structural organization of the 3TP-Lux reporter plasmid, composed of 3 AP-1 binding sites and a TGF-β–responsive PAI-1 promoter fragment driving a luciferase reporter gene, is shown. (B) Response of 3TP-Lux is increased by 4-fold in HUVECs and 10-fold in HepG2 cells after exposure to 1% O2 or TGF-β2 (12.5 ng/mL) for 24 hours. Luciferase activity was determined and results corrected to CMV promoter-responsive TGF-β2 promoter between 3 independent experiments is shown.

**Figure 7.** Hypoxia induces sequence-specific DNA binding activity by Smads. (A) Electrophoretic gel mobility shift assays were performed using a 32P-labeled SBE probe as described in “Materials and methods.” Nuclear extracts were as follows: control normoxic HUVECs, C; HUVECs treated for 30 minutes with 12.5 ng/ml TGF-β2, T; or HUVECs exposed to hypoxia (1% O2) for 4 hours, H. Competition assays: no competition (−); 100-fold molar excess of unlabeled SBE (100 × SBE); 125-fold molar excess of erythropoietin (125 × EPO), an HIF-1–containing oligonucleotide; 125-fold molar excess of an oligonucleotide that corresponds to the −77 to −40 bp TGF-β2 promoter (125 × TGF-β2). (B) Antibody supershifting: nuclear extracts from HUVECs were preincubated with anti-Smad2, anti-Smad3, or anti-Smad4 antibodies for 30 minutes prior to the binding reaction. Constitutive binding is indicated by the unlabeled arrows.
We are currently examining the effect of HIF-1α and its relative HIF-2α/endothelial PAS domain protein (EPAS) 61,62 on activity of the TGF-β2 promoter by mutating its putative HIF-1-binding sites, and after HIF-1α overexpression.

Similar to our results, up-regulation of TGF-β bioactivation by hypoxia has been shown in perivascular glial cells of retina,63 but the mechanism is unclear. One possibility is that it occurs by hypoxic stimulation of endothelial expression of thrombospondin, which activates TGF-β by alterating conformation of LAP.64 Thrombospondin transcript and protein are induced by hypoxia in a parallel time course to hypoxic activation of TGF-β2, with peak thrombospondin mRNA levels observed at 48 hours and protein levels at 72 hours.65 Interestingly, a hypoxia-induced increase in steady-state TSP-1 transcript levels is to some extent due to increases in mRNA stability.65 The possibility also exists that cellular redox states altered by hypoxia-induced gene activation and generation of reactive oxygen intermediaries, or changes in nitric oxide concentration, or inadvertent reoxygenation of HUVECs during our experiments contribute to bioactivation of TGF-β2.76,66 These possibilities are to be explored. Hypoxia causes an up-regulation of TGF-β2 expression in peritoneal mesothelial cells67 and down-regulates it in retinal cells68 and in dermal fibroblasts, where type II receptor mRNA was also found to be decreased.69 These results reflect the cell-specific nature of regulation of TGF-β genes within different contexts,77 including hypoxia. Recently, Smad2 binding to nuclear coactivator p300/CREB-binding protein was shown to inactivate nuclear factor-κB in endothelial cells in vitro and in vivo.71 It is possible that hypoxia-mediated changes in levels of transcriptional coactivators such as p300/CREB-binding protein79 may represent one mechanism responsible for cell- and context-specific actions of TGF-β2 in response to hypoxia.

Nonuniform responses in key endothelial functions such as endothelial cell growth, development, migration, and angiogenesis in response to TGF-β isoforms71,72 indicate that isoform-specific responses are biologically important. Prior to binding to TGF-βRII, TGF-β2 is anchored by membrane proteins73 or membrane or matrix proteoglycans, such as type III receptor (betaglycan),74,75 endoglin,73 biglycan, decorin, and fibromodulin.71,76 Therefore, hypoxia-induced regulation of these proteins can differentially modulate local concentrations of active TGF-β2 which, as suggested by Roberts,17 is pivotal in regulation of its actions.

Our studies do not address the consequences of Smad activation and TGF-β2 production on functions of hypoxic endothelial cells; these experiments are under way. A recent study has shown that TGF-β2 gene is specifically induced after infection of HUVECs with an adenovirus gene transfer vector that confers prolonged survival to endothelial cells even in the absence of serum.77 Furthermore, exposure of endothelial cells to TGF-β2 was shown to counteract the angiogenic effects of hepatocyte growth factor via inhibition of its signaling,78 and antibody to TGF-β2 was shown to stimulate DNA synthesis in pericytes.79 Based on these and previous findings regarding the anti-inflammatory role of the TGF-β family of cytokines,75,80-82 we hypothesize that TGF-β2 induces an antiproliferative, antiapoptotic, and antiangiogenic signal to mitigate the inflammatory signals induced by hypoxia and augments an adaptive response in the endothelium. Similar to other adaptive responses, TGF-β2 response if prolonged or unopposed can result in progressive fibrosis and vascular thickening.83,84 Understanding hypoxia-driven signaling by Smads can thus help elucidate the context and isoform-specificity of TGF-β2 actions in the vascular system and in the context of endothelial functions including tumor angiogenesis.15
