Tetra-arsenic tetra-sulfide for the treatment of acute promyelocytic leukemia: a pilot report

Dao-Pei Lu, Jing-Ying Qiu, Bin Jiang, Qin Wang, Kai-Yan Liu, Yan-Rong Liu, and Shan-Shan Chen

In the past 6 years, we treated 129 patients who had acute promyelocytic leukemia (APL) with a new arsenic agent, oral tetra-arsenic tetra-sulfide (As₄S₄). Nineteen of the patients had newly diagnosed APL, 7 had first relapse, and 103 had hematologic complete remission (HCR). HCR was achieved in all patients with newly diagnosed APL and in all those with hematologic relapse. Of 16 patients with newly diagnosed disease and available cytogenetic and molecular analyses, 14 had cytogenetic and molecular complete remission (CR). Cytogenetic and molecular CR was also obtained in 5 of the 7 patients with hematologic relapse. In the HCR group, 35 of 44 patients positive for PML-RARα at baseline became negative. In the newly diagnosed group, estimated disease-free survival (DFS) rates for 1 and 3 years were 86.1% and 76.6%, respectively, with a median follow-up time of 13.5 months (range, 2-40 months). In the HCR group, DFS rates for 1 and 6 years were 96.7% and 87.4%, respectively, with a median follow-up of 23 months (range, 2-71 months). Treatment with As₄S₄ was well tolerated, with only moderate side effects, including asymptomatic prolongation of corrected QT interval, transient elevation in liver enzyme levels, rash, and mild gastrointestinal discomfort; neither myelosuppression nor appreciable long-term side effects occurred. Degeneration or apoptosis of APL promyelocytes was observed during As₄S₄ therapy. Pharmacokinetic studies showed that the agent was absorbed rapidly. Most urinary arsenic excretion occurred within the first 24 hours. Both blood and urinary arsenic levels declined after discontinuation of As₄S₄. Our results show, for the first time, that As₄S₄ treatment alone is highly effective and safe in both remission induction and maintenance therapy in patients with APL, regardless of disease stage. (Blood. 2002; 99:3136-3143)

Introduction

Acute promyelocytic leukemia (APL), first recognized as a distinctive clinical entity in the 1950s, comprises about 10% of cases of acute myelocytic leukemias in adults. Combination treatment with all-trans-retinoic acid (ATRA) and chemotherapy has dramatically improved outcome and survival in patients with APL. Despite this improvement, relapse occurs within 4 to 5 years in approximately 30% of patients given such therapy and represents a major obstacle to cure. Investigators in China and the United States have reported that daily intravenous infusions of arsenic trioxide (ATO) induce complete remission (CR) in more than 80% of patients with relapsed and refractory APL, with an acceptable toxicity profile given the seriousness of the disease. The main toxic effects of ATO are fluid retention, hyperleukocytosis, gastrointestinal discomfort (nausea, vomiting, and diarrhea), fatigue, hyperglycemia, and neuropathy. Prolongation of the corrected QT interval (QTc), occasional liver damage, and sudden death have also been observed. In general, drug-related toxicity decreases during consolidation and maintenance courses of ATO compared with induction courses in cases of relapse. A drawback of ATO is that it must be administered intravenously daily in a 1- to 4-hour infusion. Thus, an oral agent with similar effectiveness and fewer side effects would provide not only cost and quality-of-life benefits but also easy access to consolidation and maintenance therapy.

Realgar, the ore composed mainly of tetra-arsenic tetra-sulfide (As₄S₄), has been used as a traditional medicine in China for more than 1500 years. In addition to As₄S₄, realgar contains up to about 10% of other ingredients, such as different types of arsenite, arsenic trioxide, and other minerals. Rather than being used alone to treat various diseases, realgar was commonly administered with several Chinese herbs. No previous study of the use of As₄S₄ as a single agent to treat disease has been reported. In the past 6 years, we administered an oral preparation of highly purified crystalline As₄S₄ to patients with different stages of APL. This pilot study found that oral As₄S₄ used alone is highly effective and safe for both remission induction and maintenance in all stages of APL.

Patients, materials, and methods

Patients

A total of 129 patients with APL were entered into this study between December 1994 and December 2000. Informed consent to participate was obtained from all patients. The diagnosis of APL was based on morphologic characteristics of the French-American-British classification AML-M3, cytogenetic or fluorescence in situ hybridization (FISH) analysis of t(15;17), and reverse transcription–polymerase chain reaction (RT-PCR) analysis for PML-RARα transcript. All patients with a confirmed diagnosis of APL and evidence of t(15;17) were eligible for enrollment regardless of disease stage, except for those who were unlikely to survive induction therapy because of coma or severe disseminated intravascular coagulation (DIC), those with an infection not controlled by antimicrobial therapy, those...
with an uncontrolled concurrent disease, and women who were pregnant or lactating.

Initially, only patients with molecular or cytogenetic evidence of persistent residual leukemia from previous ATRA treatment and chemotherapy were entered into the As$_4$S$_4$ treatment protocol. However, after observing preliminary evidence of safety and efficacy in this poor-prognosis group, we broadened the entry criteria to include patients at all disease stages: newly diagnosed, frank hematologic relapse, and hematologic complete remission (HCR) with or without molecular CR. Patients with HCR were previously treated in our institution or were referred, chiefly for either stem cell transplantation or postremission treatment.

All 129 patients enrolled were 14 years of age or older. Nineteen had newly diagnosed untreated APL, 7 had frank hematologic relapse, and 103 had HCR. Characteristics of the patients at diagnosis are shown in Table 1.

### Monitoring

Routine examination of the patients was done as described previously.$^{27}$ Assessments included pretreatment and posttreatment chest x-ray studies, electrocardiography, and if necessary, echocardiography and other indicated studies. Complete blood counts, coagulation studies, serum chemistry analyses, urinalyses, blood smear examinations, and bone marrow (BM) aspiration or biopsy were done on the patient’s first visit and at close periodic intervals thereafter. HCR was defined as a white blood cell (WBC) count of at least $3 \times 10^9$/L and a platelet count of at least $100 \times 10^9$/L in peripheral blood and less than 5% blasts and abnormal promyelocytes in BM smears.

Cytogenetic analyses, FISH, and RT-PCR for PML-RARα were done on BM aspirates from all patients with newly diagnosed disease or relapse, as well as most patients with HCR. Follow-up studies were performed at close intervals until cytogenetic CR was achieved or when relapse was suspected. Thereafter, cytogenetic analyses were done at regular intervals.

### Cytogenetic analysis

BM cells were cultured overnight at 37°C in McCoy SSA medium supplemented with 20% fetal-calf serum for a metaphase chromosome preparation with routine G banding. Karyotypes were evaluated according to the International System for Human Cytogenetic Nomenclature.$^{28}$ At least 20 metaphases per sample were analyzed.

### FISH analysis

FISH was performed by using whole-chromosome painting probes for chromosomes 15, 17, 8, and 11 (provided by Dr Michael Speicher of Heidelberg University) and the procedure described by Pinkel et al.$^{30}$ One hundred nuclei per sample were examined.

### Flow cytometric analysis

Direct immune staining for 3-color phenotyping was done on BM aspirates. The antibodies used for these studies were CD45–peridinin chlorophyll protein, CD2–fluorescein isothiocyanate conjugated (FITC), and CD19–phycoerythrin (PE) or CD15–FITC and CD13–PE, CD33–FITC and CD11b–PE, HLA-DR–FITC and CD34–PE, CD38–FITC and CD117–PE, and isotype controls (Becton Coulter, Miami, FL). Samples were analyzed on a fluorescence-activated cell-sorter scanner flow cytometer, and data were analyzed by using Cell Quest software (Becton Dickinson, Mountain View, CA). At least 10,000 events were counted for each tube.

### RT-PCR

Heparin-treated BM aspirates were tested by RT-PCR for PML/RARα transcript as described by Biondi et al.$^{31}$ NB4 cells served as positive controls. The sensitivity of this test is 0.5 ng RNA.

### Preparation of As$_4$S$_4$

As$_4$S$_4$ was prepared from mined natural realgar under the supervision of the first author and a collaborating pharmacist. The molecular structure of As$_4$S$_4$ has been interpreted by Chia-Si Lu for more than 50 years.$^{32}$ At the beginning of the study, we used moderately purified As$_4$S$_4$ that was mixed with an equal amount (wt/wt) of ground Semen platycladi as an excipient. To avoid any possibility that trace amounts of ATO present in the initial preparation or other arsenics in “processed-to-be-refined” realgar were responsible for the observed effects, we began to use crystallized realgar with high-purity As$_4$S$_4$ as starting material beginning in January 1998. The purity of our As$_4$S$_4$ preparation was confirmed by repeated x-ray diffraction investigations (done in collaboration with the Physical Geography Institute, Chinese Academy of Sciences). The results were compatible with pure As$_4$S$_4$ standards and excluded the presence of ATO and other arsenic compounds (Lei Wen and D.-P. L., unpublished data, July 2001). Highly purified As$_4$S$_4$ was also mixed with an equal amount of ground Semen platycladi and put into capsules containing 250 mg As$_4$S$_4$.

The high-purity As$_4$S$_4$ was given to 124 patients. However, some of the patients started preliminary therapy with the moderately purified As$_4$S$_4$ and switched to the highly purified As$_4$S$_4$ when it became available. Seventeen of the 19 patients with newly diagnosed APL and 6 of the 7 patients with hematologic relapse received only the high-purity As$_4$S$_4$.

### As$_4$S$_4$ dosage and administration

As$_4$S$_4$ was orally administered for remission induction in patients with newly diagnosed APL or APL relapse at a dosage of 50 mg/kg of body weight per day, divided into 4 doses (approximately 750 mg 4 times daily), until HCR was documented. For patients with HCR, the same daily dose was given on a treatment schedule of 2 weeks on and 2 weeks off in the first year. Thereafter, the treatment break was increased to one month within 4 years. Therapy was discontinued in the fifth year.

The As$_4$S$_4$ dosage in this study was selected on the basis of results of a dose-escalation trial and studies in animals. Realgar ore has long been used in Chinese traditional medicine and regarded as a Materia medica with mild toxicity. A small study in volunteer patients showed that escalation to a dose of 200 mg/kg per day was well tolerated.

As$_4$S$_4$ indicates trans-arсенic тетра-сульфид; APL, acute promyelocytic leukemia; HCR, hematologic complete remission; BM, bone marrow; WBC, white cell count; and Hb, hemoglobin.
single dose of 60 mg/kg As₄S₄ was well tolerated. In addition, pharmaco-
netic and toxicity studies in mice showed that our highly purified As₄S₄ was
safe when administered orally: even at a dose of 1 g/kg, it was well tolerated
Concomitantly, studies in our laboratory found that As₄S₄ was effective
against the NB4 cell line (an APL cell line) in culture and NB4-induced
promyelocytes had unusual morphologic features, including (1) a
prominent nucleolus but development of irregularity of
nuclear contour and more coarseness in the chromatin strands
presence of discernible nucleoli but development of irregularity of
the nuclear contour and more coarseness in the chromatin strands
from lightly basophilic to lightly acidophilic; and (3) continued
reduction in dense granules in the cytoplasm (degranulation);
(2) more acidophilic cytoplasm, with a changed spectrum of color
(100 × 10⁹/L) was 31 days (range, 19–47 days). Blood hemoglobin
levels recovered more slowly. No patient had exacerbation of DIC.
Patients had BM CR in a median time of 50 days (range, 26 to 101
days), with a median total dose of 110.2 g (range, 37.5 to 312.5 g).
In 14 patients, normalization of BM blasts and promyelocytes
occurred within 2 months; in the other 5, this took somewhat
longer. However, the rapid improvements in clinical condition and
the decreases in the number of BM promyelocytes and blasts that
occurred in all patients during the first month of treatment warranted
continued therapy with As₄S₄ alone. The remaining
promyelocytes had unusual morphologic features, including (1) a
reduction in dense granules in the cytoplasm (degranulation);
(2) more acidophilic cytoplasm, with a changed spectrum of color
from lightly basophilic to lightly acidophilic; and (3) continued
presence of discernible nucleoli but development of irregularity of
the nuclear contour and more coarseness in the chromatin strands
than in those of APL promyelocytes in untreated patients. The
morphologic findings suggested that the leukemic promyelocytes
underwent degeneration rather than differentiation (Figure 2).

After As₄S₄ treatment, 16 of the 19 patients with newly
diagnosed APL were evaluable for disappearance of t(15;17) and
loss of the fusion transcript on RT-PCR analysis. Patient 19 could
not be assessed because it was too early in the treatment regimen,
and patients 14 and 18 did not have an available RT-PCR analysis.
Among the 16 patients studied, t(15;17) disappeared in 15 (93.7%)
within a median time of 81 days (range, 40-172 days) and was detected in one (patient 11). The PML-RAR\textsubscript{H9251} fusion transcript became undetectable by RT-PCR in 14 patients (87.5%) within a median time of 101 days (range, 45-200 days) and remained detectable in 2 patients (6 and 11). Seven patients became negative for PML-RAR\textsubscript{H9251} on RT-PCR analysis in 100 days, 3 in 100 to 150 days, and 4 in 150 to 200 days (Figure 1). More time was required for patients to become negative on RT-PCR analysis than for cytogenetic normalization.

**DFS.** After CR, all patients received only As\textsubscript{4}S\textsubscript{4} on the protocol schedule for maintenance. Follow-up data were available for 15 patients with newly diagnosed disease. Two patients (13 and 18) were lost to follow-up and 2 others (6 and 12) were excluded from the trial because of protocol violation and nonadherence to the suggested dosage during maintenance therapy. In the 15 patients with follow-up data, 3 relapses occurred. Patient 3 again became positive on RT-PCR analysis and had relapse in the 13th month after achievement of HCR. Patient 8 had relapse in the sixth month. This patient was found to have complex karyotypes at relapse and underwent BM transplantation after another CR obtained with chemotherapy. Patient 11, who had positive results on t(15;17) and RT-PCR assessments after HCR, had relapse in the third month. Thus, with a median follow-up time of 13.5 months (range, 2-40 months), the estimated DFS rates at 1 and 3 years were 86.2% and 76.6%, respectively (Figure 3).

**Patients with relapsed APL**

The enrolled patients with relapse had previously received ATRA or chemotherapy. Two were treated with ATRA and 5 with ATRA and chemotherapy before As\textsubscript{4}S\textsubscript{4} treatment began. Their clinical characteristics and time to achieve CR are shown in Table 3. After As\textsubscript{4}S\textsubscript{4} treatment, all 7 patients with relapse had HCR, in a median time of 47.5 days (range, 32-80 days, similar to that in patients with newly diagnosed APL) and with a median total dose of 50.5 g (range, 15.7-418.7 g). Cytogenetic and molecular CRs were achieved in 5 patients. For the other 2 patients, t(15;17) and RT-PCR results were not available by the cut-off date for the statistical analysis. During follow-up, one patient with relapsed APL (R3) had another relapse, in the 10th month.

**Patients with HCR**

**Maintenance efficacy.** Of the 103 patients with HCR with or without molecular or cytogenetic residual leukemia, 84 had previously been treated with both ATRA and chemotheraphy and 19 patients were previously given ATRA alone. As\textsubscript{4}S\textsubscript{4} therapy was administered in these patients in accordance with the treatment protocol. No myelosuppression occurred. Before As\textsubscript{4}S\textsubscript{4} treatment, RT-PCR analysis to detect PML-RAR\textsubscript{\alpha} messenger RNA (mRNA) yielded positive results in 44 patients and negative results in 56; 3 patients were not tested for a variety of reasons. After As\textsubscript{4}S\textsubscript{4} therapy, 35 of the 44 patients (79.5%) with positive results on RT-PCR analysis became negative on RT-PCR analysis in a median time of 114 days (range, 22-622 days; Figure 4).

**DFS.** During the entire 6-year study, 99 patients in the HCR group were available for statistical analysis, and 4 were lost to follow-up. In the entire series, there were 9 relapses, including 1 extramedullary relapse and 8 hematologic relapses. At initiation of As\textsubscript{4}S\textsubscript{4} therapy in these 9 patients, RT-PCR analysis yielded positive results in 4, negative results in 4, and was not available in one. The
extramedullary relapse occurred in the central nervous system in the 28th month after As₄S₄ therapy began. The 8 patients with hematologic relapse had a median relapse interval of 13.5 months (range, 6-22 months). Of these 8 patients, 3 had a second HCR with hematologic relapse had a median relapse interval of 13.5 months chemotherapy, or both before treatment with As₄S₄.

Typically associated with APL, were observed before As₄S₄ therapy. Among 124 patients evaluated for toxic effects of high-purity As₄S₄, most had no severe adverse events. The main side effects adverse effects

Flow cytometric studies in patients with overt APL

Flow cytometric evaluations for CD33, CD13, and CD15 were done on BM samples from 13 patients, 9 with newly diagnosed APL and 4 with relapse. CD33⁺ and CD13⁺ cells, which are typically associated with APL, were observed before As₄S₄ therapy and began to decrease after treatment, gradually reaching the normal range. Concomitantly, there was increased expression of CD15, an antigen associated with mature granulocytes (Figure 6).

Adverse effects

Among 124 patients evaluated for toxic effects of high-purity As₄S₄, most had no severe adverse events. The main side effects observed are listed in Table 4. The effect most often observed was asymptomatic QTc prolongation, which occurred in 33 of 100 patients (33%) with an available electrocardiogram and ranged from 0.440 to 0.513 seconds (median, 0.455 seconds). QTc prolongation occurred at different accumulative dosages, with the median being 76.5 g (range, 3.0-1127.5 g). However, all patients with prolonged QTc were asymptomatic and As₄S₄ treatment could be administered as scheduled. No patient had ventricular premature beats or ventricular tachycardia (including torsive ventricular tachycardia).

Another side effect was a transient elevation in liver enzyme levels, which occurred in 13 of 124 patients (10.5%). Among these 13 patients, neither hepatitis B virus (HBV) nor hepatitis C virus (HCV) infection was detected in 8, one had HBV DNA, and 4 had HCV RNA, with or without small increases in liver enzyme levels before As₄S₄ therapy. In the 8 patients without HBV or HCV infection, the elevation in serum alanine aminotransferase (ALT) and serum aspartate aminotransferase (AST) occurred on the 7th day to the 13th month after As₄S₄ therapy began. The peak ALT level ranged from 67 to 466 U/L (median, 214 U/L; normal range, 0 to 40 U/L) and the peak AST level from 51 to 435 U/L (median, 212 U/L; normal range, 0 to 40 U/L). The ALT and AST elevations lasted for 10 to 60 days. All 8 patients had recovery of normal values after conservative treatment, and they continued to receive As₄S₄ therapy after hepatic recovery. The 5 patients with HBV or HCV infection had ALT and AST elevations for longer periods. Three of those 5 patients had a small increase in ALT and AST before As₄S₄ therapy. In 2 patients, temporary discontinuation of As₄S₄ therapy was necessary.

Mild nausea without vomiting or diarrhea occurred in 4 patients (3.2%). Skin itching or puffiness of the eyelids also occurred in 4 patients (3.2%). No patient had ankle edema or peripheral neuropathy.

Neither myelosuppression nor retinoic acid syndrome was observed. As₄S₄ was given safely to patients with severe neutropenia. No patient in the HCR group had leukocytosis. However, mild and transient leukocytosis occurred in some patients with newly diagnosed APL during remission induction; these patients had an increased WBC count (> 10 × 10⁹/L) before As₄S₄ treatment (4 patients) or during As₄S₄ therapy (5 patients). A gradual increase in

---

**Figure 6.** Surface-antigen analyses of BM before and after As₄S₄ treatment. Expression of surface antigens of CD33, CD13, and CD15 in BM mononuclear cells was analyzed by flow cytometry before and after As₄S₄ treatment. Data are mean ± values from 13 patients, 9 with newly diagnosed disease and 4 with relapse. Before treatment, most cells expressed only CD33 and CD13, typical of APL. After HCR was achieved, most myeloid-lineage cells expressed CD15, the antigen usually found on mature cells.
peripheral WBC count developed, with peak values ranging from 15.1 to 45.9 \times 10^9/L on the 4th to 22nd day after As$_4$S$_4$S was given (Figure 7). In 4 patients, the elevations in WBC were easily controlled by a few doses of hydroxyurea. Patient 7 received a low dosage of harringtonine (2 mg/day) for 3 days. In 4 other patients (dotted lines in Figure 7), the high WBC resolved spontaneously, without administration of cytotoxic drugs.

One patient had a mild and non-life-threatening pericardial effusion. This patient had the same problem when previously treated with ATRA or chemotherapy. No severe persistent toxicity was observed during the 6 years of this study.

### Clinical pharmacokinetic study

Pharmacokinetic variables were analyzed in 7 volunteers with APL and HCR by using a single dose of As$_4$S$_4$. The single dose of up to 60 mg/kg As$_4$S$_4$S was well tolerated. Arsenic could be detected in the blood 30 minutes after oral administration of As$_4$S$_4$. The T$_{peak}$ was 3.4 ± 1.4 hours and the C$_{max}$ was 24.9 ± 8.0 \mu g/L. There was a wide interpatient variation in AUC$_{0-\infty}$ (899.01 ± 705.64 \mu g/hour per liter) and t$_{1/2}$ (30.1 ± 11.1 hours).

Mean ± SD levels of urinary arsenic excretion were 323.5 ± 271.8 \mu g at 0 to 4 hours, 392.9 ± 295.0 \mu g at 4 to 8 hours, 245.1 ± 157.7 \mu g at 8 to 12 hours, 582.9 ± 312.6 \mu g at 12 to 24 hours, 904.7 ± 475.8 \mu g at 24 to 48 hours, 709.4 ± 332.2 \mu g at 48 to 72 hours, and 355.9 ± 226.2 \mu g at 72 to 96 hours. To characterize arsenic excretion, we calculated percentages of daily urinary arsenic excretion of the total arsenic excreted in the first 96 hours; mean percentages were 45.5% ± 12.9% for 0 to 24 hours, 26.1% ± 8.4% for 24 to 48 hours, 20.9% ± 9.2% for 48 to 72 hours, and 7.8% ± 4.4% for 72 to 96 hours (Figure 8).

During the 2-weeks-on and 2-weeks-off treatment schedule, blood arsenic levels were measured in 8 patients in the HCR group on the 7th and 14th day after As$_4$S$_4$S began, as well as on the 7th and 14th day after therapy was discontinued (Figure 9). Mean ± SD levels were 51.9 ± 13.6 \mu g/L on the 7th day and 64.9 ± 11.4 \mu g/L on the 14th day. Blood arsenic levels decreased to 26.1 ± 6.4 \mu g/L and 13.1 ± 8.0 \mu g/L on the 7th and 14th day, respectively after discontinuation of therapy.

In 5 patients with newly diagnosed APL, plasma, red cell, and white cell arsenic levels were also measured. Baseline values were below 2 \mu g/L. On the fourth day of As$_4$S$_4$S treatment, the mean level of arsenic in red cells rose to 22.65 ± 2.65 \mu g/L, and the plasma arsenic level was 8.6 ± 6.9 \mu g/L. Both arsenic levels increased gradually, to 90.9 ± 4 \mu g/L in red cells and 20 to 31 \mu g/L in plasma on the 40th day of continuous treatment and plateau levels thereafter. The red cell arsenic level was 2.1 ± 3.6 times higher than the plasma level. During treatment, the mean urinary arsenic level on the eighth day was 1733.6 ± 1365.9 \mu g/L (44 samples), and the average daily urinary excretion was 3.93 ± 2.44 mg/day. The urinary excretion level fell to 0.33 ± 0.3 mg/day 8 days after therapy was discontinued. The arsenic level in cerebrospinal fluid in 9 patients on the 10th day of treatment was 5.6 to 14.6 \mu g/L, a level similar to that in plasma. The mean arsenic level in hair (13 patients) was 3.7 ± 1.5 \mu g/g in the 4th month and accumulated to 13.5 ± 7.8 \mu g/g in the 18th month.
Discussion

ATO has been reported to induce clinical and molecular remission in a high proportion of patients with APL. Because ATO can cause severe liver damage if given orally, the agent must be administered intravenously. However, high doses of intravenous ATO may be associated with serious acute toxicity. Administration of ATO requires close monitoring. On the other hand, we found in this series of patients with APL that oral As₄S₄ is effective and easy to administer, so that quality of life is improved, especially in patients in whom long-term therapy is required.

We conducted a 6-year study of treatment of APL with an oral preparation of As₄S₄. The therapeutic effect of As₄S₄ is well established. In our study, As₄S₄ used alone not only induced HCR in all patients with newly diagnosed and relapsed APL but also produced cytogenetic and molecular CR in 87.5% of patients with newly diagnosed disease and in most evaluable patients with hematologic relapse. In treatment for residual leukemia, 79.5% of patients in this series who had PML-RARα mRNA transcript at baseline became negative for PML-RARα mRNA after As₄S₄ treatment. Used as a single agent, As₄S₄ was associated with long-term DFS rates, including 86.1% and 76.6% at 1 and 3 years in the patients with newly diagnosed disease and 96.7% and 87.4% at 1 and 6 years in the HCR group. Without a randomized clinical trial, it is not possible to determine the relative efficacy of As₄S₄ and ATO. However, both agents appear to induce a high proportion of durable remissions in patients with APL refractory to ATRA and chemotherapy.

Realgar, a mined ore, contains about 90% As₄S₄. Realgar has been used in Chinese traditional medicine for more than 1500 years. Employed either externally or orally, realgar was administered to treat a variety of diseases, including syphilis, “malignant” sores, malaria and several other parasitic infections, and was regarded as having little toxicity. It was also claimed to be effective against certain “malignant” diseases in which persistent fevers and large intra-abdominal masses occurred. In provinces south of the Yangtze River, realgar was regularly used at home for sores, malaria and several other parasitic infections, and was regarded as having little toxicity. It was also claimed to be effective against certain “malignant” diseases in which persistent fevers and large intra-abdominal masses occurred. In provinces south of the Yangtze River, realgar was regularly used at home during the Duan-Wu festival. Realgar in wine, in which some of the agent was dissolved and some suspended to make “realgar wine,” was used as a preventive against “malignant influences.” A suspension of realgar was sprinkled on the ground to keep out insects and snakes. These historical uses demonstrate the relatively nontoxic nature of realgar compared with ATO administered orally.

It is recorded in ancient Chinese Materia medica books that excavated realgar is toxic or mildly toxic. Before this agent is made available on the traditional Chinese pharmacy market, it must be “refined” in accordance with methods used in traditional Chinese medicine. Unrefined realgar contains appreciable amounts of ATO, as well as calcium and magnesium arsenites, which are toxic. Use of realgar as mined can produce toxic effects. Realgar differs greatly in the purity of its As₄S₄ contents. Mineral crystal with a very high proportion of As₄S₄ was rarely used in Chinese traditional medicine. Although realgar was used commonly, it was employed with several herbal drugs containing hundreds of components. Neither As₄S₄ nor other arsenic sulfides, such as diarsenic trisulfide (As₂S₃), were previously described as being effective against any malignant disease when used alone.

During treatment of APL in our series, As₂S₃ was well tolerated, with moderate side effects. As₂S₃ caused QTc prolongation in 33% of patients, but neither symptoms nor serious cardiac events occurred. The incidence and severity of QTc prolongation appear to have been lower than with ATO. In ATO treatment, a marked percentage of cases of QTc prolongation and even torsades de pointes were reported. The mechanism of QTc lengthening with As₂S₃ is unknown and must be elucidated.

With respect to hepatotoxicity, As₄S₄ treatment led to transient injury. Patients with elevations in liver enzyme levels after As₄S₄ treatment had recovery within 10 to 60 days after conservative treatment. This effect was not related to cumulative doses of As₂S₃. Patients with concomitant with HBV or HCV infection were vulnerable to hepatic injury. Importantly, neither retinoic acid syndrome nor myelosuppression occurred during the treatment course. Only a mild, transient leukocytosis was detected in patients with newly diagnosed disease during remission induction. The WBC counts returned to normal levels spontaneously or after a few small doses of cytotoxic drugs. It is important to note that ATRA and even ATO were found to induce a level of hyperleukocytosis that was more severe and was responsible for early deaths during remission induction; this was especially true of ATRA.

Orpiment has been used as a Chinese Materia medica for nearly as long as realgar. A major ingredient of orpiment, could also be used either externally or orally. The Chinese name for orpiment is literally translated as “female yellow,” whereas that for realgar is “male yellow.” In the current study, we treated one patient with newly diagnosed APL with synthetic, chemically pure As₂S₃. The patient had HCR and molecular CR after monotherapy with As₂S₃. Therefore, this form of arsenic sulfide may also be an effective therapy for APL.

The morphologic appearance of APL promyelocytes after As₄S₄ treatment suggested degeneration and apoptosis rather than differentiation. As₂S₃ and As₂S₅ have induced subdiploid cells, DNA ladder formation on agarose-gel electrophoresis, and enhancement of caspase-3 activity in the NB4 cell line. Arsenic sulfides also arrested NB4 cell growth in the G₂/M phase. Relocalization of PML protein in patients’ APL cells was detected readily in cells from BM aspirates from patients treated with arsenic sulfides before the morphologic change. The decrease in promyelocytes and blasts in the BM obtained after As₂S₃ therapy in patients with APL was accompanied by a reduction in t(15;17) cells. Clinical improvement and platelet recovery usually preceded the decrease in promyelocytes.

Our pharmacokinetic studies revealed that rapid absorption of arsenic occurred after oral administration of As₂S₃. A single large dose of arsenic sulfide in 7 patients with APL produced similar and tolerable peak blood arsenic levels without appreciable side effects. Intervariant variations in arsenic absorption, metabolism, and clearance were observed. However, when As₂S₃ was administered daily in divided doses, blood levels were not only tolerable but fell within a certain range. Both blood and urinary arsenic levels declined after As₂S₃ was discontinued. Because 70% of absorbed arsenic is excreted in urine by means of the kidneys, we deduce that 5.61 ± 3.4 mg arsenic was absorbed from the intestinal tract each day by each patient in our series. On the other hand, because of the renal excretion of arsenic, the dosage should be adjusted for diminished renal function. Arsenic binds keratoprotein and can be removed through hair and nail growth and cutaneous surfaces. In this study, continuous use of oral As₂S₃ was associated with increased elimination of arsenic in hair. Together with the renal excretion of arsenic, this at least partly accounts for the flattening out or lessening of increases in arsenic levels. Additional studies of the metabolism and clearance of arsenic in humans requires further investigation.

Our findings lead us to conclude that oral As₂S₃ is highly
effective in inducing CR both in patients with newly diagnosed APL and in those with APL relapse. Moreover, it is highly effective in treating residual APL and for CR maintenance. Blood and BM cell morphologic characteristics, t(15;17), and PML-RAR results on RT-PCR analysis became normal in patients with APL after As₄S₄ treatment. Oral arsenic can be used safely for induction or long-term treatment in most patients with APL. The highly purified arsenic used at the dosages described here produced no symptoms, signs, or laboratory evidence of adverse effects in most patients. No myelosuppression was observed, in contrast to results with other cytoxic anticancerogenic agents. An honorable gift from nature, As₄S₄ must be added to the list of effective therapeutic agents for the cure of APL.

Acknowledgments

We thank Drs Xiao-Jun Huang, Xi-Jing Lu, and Wei Han for valuable assistance in the clinic; Hui-Lin Shi, Xiao-Ying Qin, Ya-Zhen Qin, Guo-Xuan Li, Bo Hong, and Feng-Rong Wang for helpful laboratory work; and Drs Peggy Pei-Hua Lu and Yan-Fang Liu for assistance in preparation of the manuscript.
