Elevated serum tryptase levels identify a subset of patients with a myeloproliferative variant of idiopathic hypereosinophilic syndrome associated with tissue fibrosis, poor prognosis and imatinib-responsiveness
Since serum tryptase levels are elevated in some patients with myeloproliferative disorders, we examined their utility in identifying a subset of patients with hypereosinophilic syndrome (HES) and an underlying myeloproliferative disorder.

Elevated serum tryptase levels (>11.5 ng/ml) were present in 9/15 patients with HES and were associated with other markers of myeloproliferation, including elevated B12 levels and splenomegaly. Although bone marrow biopsies in these patients showed increased numbers of CD25+ mast cells and atypical spindle–shaped mast cells, patients with HES and elevated serum tryptase could be distinguished from patients with systemic mastocytosis and eosinophilia by their clinical manifestations, the absence of mast cell aggregates, the lack of a somatic KIT mutation and the presence of the recently described FIP1L1-PDGFRA fusion. Patients with HES and elevated serum tryptase were more likely to develop fibroproliferative end organ damage, and 3/9 died within 5 years of diagnosis in contrast to 0/6 patients with normal serum tryptase levels. All 6 patients with HES and elevated tryptase treated with imatinib demonstrated a clinical and hematologic response. In summary, elevated serum tryptase appears to be a sensitive marker of a myeloproliferative variant of HES that is characterized by tissue fibrosis, poor prognosis, and imatinib responsiveness.
Introduction

Hypereosinophilic syndrome (HES) is a term applied to a heterogeneous group of disorders defined by: 1) the presence of eosinophilia (>1500 eosinophils/mm³ for at least 6 months) that remains unexplained despite a comprehensive evaluation for known causes of eosinophilia and 2) evidence of organ dysfunction directly attributable to the eosinophilia or otherwise unexplained in the clinical setting. Although the etiology of HES is unknown, the recent identification of subgroups of patients with HES and clonal populations of eosinophils or lymphocytes suggests that patients with HES can be separated into at least two major subgroups: those with a primary disorder of myelopoiesis and those with secondary eosinophilia due to overproduction of eosinophilopoietic cytokines by a clonal population of lymphocytes. Using currently available techniques, however, clonal populations of cells are not readily identifiable in a majority of patients with HES.

The clinical manifestations and responses to therapy in patients with HES are highly variable and likely reflect, at least in part, the underlying etiology of the disorder in a given patient. This has become even more evident with the recent description of FIP1L1-PDGFR, a constitutively activated tyrosine kinase created by an interstitial deletion on chromosome 4q12, that is associated with imatinib-responsiveness in some patients with HES. Several clinical markers of poor prognosis have been identified, including the lack of a response to steroids, a markedly elevated white blood cell count, and a normal IgE level, although the relationship of these markers to disease pathogenesis has not been explored.
Some patients with hypereosinophilic syndrome have features of an underlying myeloproliferative disorder, including the presence of increased early myeloid precursors in the peripheral blood and bone marrow, and elevated serum B12 levels. In contrast to patients with chronic myeloid leukemia, however, these patients exhibit no evidence of cytogenetic abnormalities or increased numbers of blasts. Since serum tryptase levels are elevated in some myeloproliferative disorders, we examined the utility of serum tryptase levels in identifying the subset of HES patients with a primary myelopoietic disorder. The clinical and laboratory features of this group of patients were compared to those of patients with HES and normal serum tryptase levels, and to patients with systemic mastocytosis and eosinophilia >1,500/mm³.

**Patients and methods**

**Patient populations.** All study participants were evaluated at the National Institutes of Health (NIH), Bethesda, MD between 1994 and 2002 as part of research protocols designed to study the pathogenesis of eosinophilic disorders, helminth infections or mastocytosis. Thirty-two patients had at least two documented absolute peripheral blood eosinophil counts >1500/mm³ and were included in the analysis. HES was defined as 1) peripheral blood eosinophilia > 1,500/mm³ on two occasions at least 6 months apart, 2) no known etiology for the eosinophilia despite careful clinical evaluation, 3) evidence of end organ damage (histologic evidence of tissue infiltration by eosinophils and/or objective evidence of clinical pathology in any organ system that is temporally associated with eosinophilia and not clearly attributable to another cause), 4) no evidence of a clonal hematopoietic process as determined by cytogenetic analysis of unstimulated bone marrow cells (a minimum of 20 metaphases), PCR-based TCR gamma receptor and
immunoglobulin heavy chain gene rearrangement analysis of PBMC and/or bone marrow aspirates and flow cytometric analysis of T cell surface markers (CD3, CD4, CD8, CD25 and HLA-DR) and 5) clinical and/or laboratory findings inconsistent with other idiopathic eosinophilic disorders, including Churg-Strauss vasculitis, chronic eosinophilic pneumonia, eosinophilic gastroenteritis and episodic angioedema and eosinophilia.

All laboratory testing reported in this study was performed in the Clinical Pathology Departments at the NIH Clinical Center, with the exception of serum total tryptase levels, which were measured at the Mayo Medical Labs (Rochester, MN). The normal range for serum tryptase used in this study (<11.5 ng/ml) was provided by Mayo Medical Labs. Splenomegaly was assessed by physical examination and confirmed by computed tomography (CT). Pulmonary disease was classified as restrictive or obstructive on the basis of characteristic findings on pulmonary function testing (PT), including spirometry, flow volume loops and assessment of diffusion capacity. Interstitial infiltrates on chest CT were considered supportive evidence of restrictive disease, but were not sufficient for classification in the absence of PFT abnormalities.

**Mutational analysis of KIT.** Bone marrow mast cells were enriched based on their surface CD25 expression. Bone marrow aspirate mononuclear cells were isolated by Ficoll-Hypaque density gradient (1.077). CD25 positive cells were then separated using anti human CD25 coated paramagnetic beads according to the manufacturer's instructions (Miltenyi Biotec, Auburn, CA). Purified mast cells were obtained first by anti-CD25 magnetic bead selection as described followed by flow cytometric sorting based on high CD117 expression. Total RNA was isolated from peripheral blood mononuclear cells,
Bone marrow CD25+ cells or purified mast cells using RNeasy kit (Quiagen, Valencia, CA). RT-PCR and restriction fragment length polymorphism analysis of the PCR products for Asp816Val KIT mutation were performed as described. In some patients, direct sequencing of the PCR fragments were performed using an ABI Prism 310 Genetic Analyzer (Applied Biosystems, Foster City, CA) and a Big Dye Terminator DNA sequencing kit (Applied Biosystems).

Flow cytometric analysis of mast cells. Bone marrow aspirates were obtained from patients following informed consent. The bone marrow aspirate mononuclear cell fraction containing mast cells was then separated using Histopaque (density=1.077, Sigma, St. Louis, MO) gradient centrifugation, and contaminating red cells were lysed by incubation in 0.8% ammonium chloride solution (Stem Cell Technologies, Vancouver, BC, Canada) for 10 min. Mast cells in bone marrow aspirates were identified by flow cytometry as a CD117+, high side-scatter population as described. Briefly, bone marrow mononuclear cells were incubated in 100 microliter aliquots for 30 min at 4°C with a phycoerythrin (PE) conjugate of anti-human CD117 (Clone 104D2, Becton-Dickinson, San Jose, CA) and a FITC conjugate of anti-human CD2, CD25 or CD35 (BD Pharmingen, San Diego, CA). The cells were then washed, resuspended in phosphate buffered saline (PBS) containing 0.1% bovine serum albumin (BSA), and analyzed on a flow cytometer (FACScan, Becton Dickinson).

Detection of FIP1L1-PDGFRA fusion. RNA was isolated from peripheral blood mononuclear cells using Trizol (invitrogen). First strand cDNA was synthesized from 2 µg of total RNA using Superscript first-strand synthesis system (Invitrogen) with random primers. Fusion of FIP1L1 to PDGFRA was analysed by nested PCR using...
primers FIP1L1-F1 (5'-acctggtgctgatctttctgat) and PDGFRA-R1 (5'-
tgagagctgtttttcactgga) during the first PCR, and primers FIP1L1-F2 (5'-
aaagaggatacgaatgggacttg) and PDGFRA-R2 (5'- gggaccggcttaatccatag) for the second
PCR. Control RT-PCR for GAPDH was performed using the primers GAPDH-F (5'-
tggaatcccatcaccatct) and GAPDH-R (5' - gtcttctgggtggcagtgat). PCR products were
cloned in pGEM-T-easy (Promega) and cloned products were sequenced on an ABI
system (Perkin Elmer).

Statistical analysis. Nonparametric comparisons of group means were made using the
Mann-Whitney U test. Correlations between observations were determined by
Spearman’s rank correlation coefficient. Contingency table analyses were performed by
Fisher’s exact test. A P value of < 0.5 was considered statistically significant for all tests.

Results

Detection of elevated serum tryptase levels in a subset of patients with HES.

Serum tryptase levels were measured in 32 patients with peripheral eosinophil
counts ≥ 1500/mm3, including 15 patients with HES, 6 patients with documented
helminth infection, 3 patients with systemic mastocytosis and eosinophilia, and 8 patients
with other disorders associated with eosinophilia (Table 1). Elevated serum tryptase
levels (>11.5 ng/ml) were found in 9 of the 15 patients with HES and both patients with
systemic mastocytosis (Figure 1). One patient with eosinophilic gastroenteritis and an
elevated peripheral blood eosinophil count also had a mildly elevated serum tryptase
level of 18.7 ng/ml (Figure 1). Of note, serum tryptase levels in the three patients with
systemic mastocytosis and eosinophilia were markedly increased (143, 205 and 675
ng/ml) as compared to the patients with HES and elevated serum tryptase levels (median 28 ng/ml, range 19–44 ng/ml; p = 0.03).

**Association of elevated serum tryptase levels in patients with HES with features of myeloproliferative disease and poor prognosis**

Patients with HES were divided into two groups based on the presence or absence of elevated serum tryptase levels (n = 9 and 6, respectively). As shown in Table 2, all 9 of the patients with elevated tryptase were male, in contrast to 1 of the 6 patients with normal tryptase levels (p <0.008). There was no difference in median age between the two groups. End organ manifestations of HES in patients with elevated tryptase included biopsy-proven endomyocardial fibrosis (n =3), restrictive pulmonary disease (n = 4), mucosal ulcerations (n = 3) and splenomegaly (n = 7) (Table 3). None of these manifestations were identified in patients with HES and normal tryptase levels, who typically presented with obstructive pulmonary disease (n = 3), pruritic dermatitis (n = 6) and gastrointestinal complaints (n = 4). Three of the 9 patients with HES and elevated serum tryptase died of complications of HES within 5 years of their diagnosis, in contrast to 0/6 patients with HES who had normal serum tryptase levels.

HES patients with elevated tryptase levels had increased median white blood cell and eosinophil counts and decreased platelet counts as compared to patients with normal tryptase levels (Table 2). In addition, all of the patients with HES who had elevated serum tryptase, and none of those without elevated serum tryptase, had myelocytes and/or promyelocytes detectable on peripheral smear. Median hemoglobin and IgE levels were also decreased in the patients with HES and elevated serum tryptase, although these relationships did not reach statistical significance (p = 0.08).
Elevated serum B12 levels are seen in association with a variety of myeloproliferative diseases\textsuperscript{13}, and have been described in patients with HES\textsuperscript{14}. Serum B12 levels were markedly increased in all of the patients with HES and elevated serum tryptase levels (median 5766 pg/ml, range 2,000-27,529, normal values 220-960). In contrast, serum B12 levels were mildly elevated in only 2 patients with HES with normal serum tryptase levels (median 802, range 374-1135).

Bone marrow biopsies from patients with HES with and without elevated serum tryptase levels were compared. The bone marrow biopsies of patients with HES and increased serum tryptase levels were more likely to be hypercellular with increased and left shifted eosinophils (7/9 vs 1/4), have increased reticulin fibrosis (5/9 vs 0/4), increased atypical mast cells (spindle shaped) (8/9 vs 0/4) and increased small lymphocytes (4/9 vs 0/4) than biopsies from patients with HES and normal serum tryptase levels (Table 2; Figure 1).

**Correlates of elevated serum tryptase in patients with HES**

Although patients with HES and elevated serum tryptase levels had increased absolute eosinophil counts when analyzed as a group as compared to patients with HES and normal tryptase levels, serum tryptase levels did not correlate with absolute eosinophil counts in the group as a whole ($r <0.2$; data not shown) or at the individual patient level. In fact, serial tryptase levels continued to rise (from 27.1 to 35.6 to 47.5) in one patient who experienced progression of disease, despite a decrease in eosinophilia from 7,500/mm$^3$ to 1,500/mm$^3$ over a 7 month period. Basophils, a potential source of serum tryptase\textsuperscript{15}, were not increased in the peripheral blood of any of the patients studied.
and were similar in number in patients with HES with and without elevated serum tryptase levels (Tables 1 and 2).

Both mast cells and myeloblasts have been reported to produce tryptase. Consequently, bone marrow biopsies from all study patients for whom sections were available were stained with anti-tryptase antibody. Increased numbers of spindle-shaped mast cells were seen in the biopsies of 8/9 patients with HES and elevated serum tryptase levels, although mast cell aggregates characteristic of systemic mastocytosis were notably absent (Figure 2). Mast cell morphology and numbers were normal in the biopsies of HES patients without elevated serum tryptase levels (n = 4).

**HES with increased serum tryptase is a clinical syndrome that is distinct from systemic mastocytosis**

The clinical manifestations of systemic mastocytosis include characteristic skin lesions (urticaria pigmentosa), malabsorption with weight loss, hepatomegaly with ascites, splenomegaly and pathologic fractures. With the exception of mild splenomegaly, which was identified in 7 of 9 patients with HES and elevated tryptase levels, clinical findings typical of mastocytosis were notably absent in these patients. Furthermore, skin biopsies were performed in all patients with HES who had dermatitis or mucosal ulcerations and revealed no evidence of increased or atypical mast cells (data not shown).

Since aberrant co-expression of CD2 and CD25 on the surface of bone marrow mast cells has been described as a feature characteristic of systemic mastocytosis, flow cytometry was performed on mast cells from the bone marrow aspirates of 4 patients with HES and elevated serum tryptase levels and 3 patients with systemic mastocytosis.
and marked eosinophilia. In all 4 patients with HES, CD25 expression was detected on CD117+CD34- bone marrow mast cells in the absence of CD2 expression (Figure 3). In contrast, bone marrow mast cells from the 3 patients with systemic mastocytosis and eosinophilia co-expressed CD2 and CD25.

Somatic KIT mutations at the amino acid position D816 (single-letter amino acid code) are detectable in most adult patients with systemic mastocytosis. The presence of this 816 mutation in KIT was assessed by restriction fragment length polymorphism analysis of cDNA obtained from peripheral blood mononuclear cells (n=1) or bone marrow mononuclear cells enriched for cells expressing CD25 on their surface (n=3) from patients with HES and elevated serum tryptase. No codon 816 KIT mutations were detected by RT-PCR in cells from any of the 4 patients with HES (Table 4). The absence of a codon 816 KIT mutation was confirmed by direct sequencing of the cDNA in 2 of the patients with HES and elevated serum tryptase. In contrast, a codon 816 KIT mutation was present in unfractionated peripheral blood mononuclear cells (n=2) or purified mast cells (n=1) in all 3 of the patients with systemic mastocytosis and eosinophilia (Table 4).

**Elevated tryptase levels are associated with imatinib-responsiveness and expression of FIP1L1-PDGFRA in patients with HES**

In view of the clinical and laboratory data supporting a myeloproliferative pathogenesis for HES with elevated tryptase and case reports demonstrating a response to imatinib mesylate therapy in some patients with HES, 6 patients with HES and elevated tryptase were treated with imatinib mesylate 400 mg daily. Symptoms resolved in all patients within a week of the initiation of imatinib therapy. Eosinophil counts normalized
MYELOPROLIFERATIVE HYPEREOSINOPHILIC SYNDROME

(<750 eosinophil/mm3) in 5/6 patients within a week of the initiation of imatinib therapy. The sixth patient, whose eosinophil count had normalized on cyclosporin A and interferon therapy, had an initial increase in peripheral eosinophilia at 1 week, followed by a return to normal (<750/mm3) by 3 weeks post-treatment. Of note, serum tryptase levels remained elevated in all 6 patients prior to the initiation of imatinib therapy despite treatment with steroids (n = 2), interferon (n= 2), hydroxyurea (n= 4), and cyclosporin (n= 1) and normalized within a week of imatinib therapy in all patients.

FIP1L1-PDGFR, is a constitutively activated tyrosine kinase created by an interstitial deletion on chromosome 4q12, that is associated with imatinib-responsiveness in some patients with HES. The presence of this fusion was assessed by reverse transcriptase PCR using RNA isolated from PBMC from 5 patients with HES and elevated serum tryptase (4 of whom had demonstrated a clinical response to imatinib and 1 who died before imatinib was available), 4 patients with HES and normal serum tryptase levels and 2 patients with familial eosinophilia, an autosomal dominant disorder that has been mapped to chromosome 5q31-33. The fusion was detected in RNA from all 5 of the patients with HES and elevated serum tryptase and in none of the patients with HES and normal serum tryptase or familial eosinophilia (Figure 4A). Sequence analysis confirmed that all breakpoints in PDGFRA occurred in exon 12 and that all of the fusions were in-frame (Figure 4B).

Discussion

The existence of a subset of patients with HES and features of myelodysplasia, including splenomegaly and increased vitamin B12 levels, has long been recognized. These features, as well as male gender, have also been associated with progression to
endomyocardial fibrosis, although the mechanism underlying this link is poorly understood. As has been shown for serum B12 levels, elevated serum tryptase levels identify a subgroup of patients with other evidence of myeloproliferative disease, including splenomegaly, marrow hypercellularity, and the presence of early myeloid precursors on peripheral smear (Table 1). Interestingly, they are also associated with male gender, clinical manifestations of tissue fibrosis and poor prognosis, and the presence of the FIP1L1-PDGFR fusion tyrosine kinase associated with imatinib-responsiveness in HES.

Although serum total tryptase is produced predominantly by mast cells, other cell types, including basophils and myeloblasts, can produce tryptase. Eosinophil production of tryptase has not been described, and the lack of correlation between peripheral blood eosinophil counts and serum tryptase levels suggests that eosinophils are not the source of the elevated serum tryptase in patients with HES. This is further supported by immunohistochemical studies of the bone marrow biopsies from HES patients with elevated serum tryptase levels, which show tryptase expression in mast cells, but not in eosinophils or their precursors.

Since eosinophilia, at times marked, has been described in patients with systemic mastocytosis, an extensive evaluation, based on recently published consensus diagnostic criteria, was performed to exclude systemic mastocytosis in the subgroup of patients with HES who had elevated tryptase. Although multifocal dense infiltrates of mast cells were not detected in the bone marrow biopsies or other tissues in these patients, three of four minor criteria (>25% of bone marrow mast cells are atypical...
or spindle-shaped, KIT+ mast cells coexpress CD2 and/or CD25, and serum tryptase persistently > 20 ng/ml) were present in all patients. Although the presence of three minor criteria would allow for a diagnosis of systemic mastocytosis using the currently accepted diagnostic criteria 17, several features distinguish patients with HES with elevated serum tryptase from those with systemic mastocytosis with eosinophilia suggesting that the two syndromes have different underlying etiologies and pathogenesis. First, in contrast to patients with systemic mastocytosis, who typically present with symptoms and signs related to mast cell infiltration of tissues and histamine release, patients with HES and elevated tryptase develop end organ damage characterized by eosinophilic infiltration of tissues and/or deposition of eosinophil granule proteins. Second, CD117+CD34- bone marrow mast cells from most patients with systemic mastocytosis co-express CD2 and CD25 12; whereas, CD2 was not detected on mast cells from any of the patients with HES and elevated tryptase. Third, a codon 816 KIT mutation was not detectable in bone marrow mononuclear cells enriched for CD25+ aberrant mast cells. This mutation is almost always detectable in lesional mast cells in patients with systemic mastocytosis and was present in mast cells from all 3 of the patients with systemic mastocytosis and eosinophilia. Finally, tryptase levels were significantly higher in all four patients with unexplained eosinophil counts >1500/mm3 and systemic mastocytosis (diagnosed on the basis of characteristic clinical signs and symptoms and the presence of mast cell infiltrates in the bone marrow) than in the patients with HES and elevated serum tryptase (Figure 1).
There is substantial evidence that eosinophils and mast cells interact at sites of allergic inflammation, and recent studies have demonstrated that eotaxin, a chemokine central to the accumulation of eosinophils at sites of tissue inflammation, also acts on mast cells. Not only do mast cells secrete a wide variety of cytokines and chemokines involved in eosinophil production, activation and survival (e.g. IL-5, IL-3, and GM-CSF), but eosinophils synthesize and release mast cell growth factors, including stem cell factor (SCF) and nerve growth factor (NGF). Furthermore, the eosinophil granule proteins, major basic protein (MBP) and eosinophil cationic protein (ECP), can activate mast cells to secrete histamine, tryptase and prostaglandin PGD2, an effect that appears to be modulated by fibroblast-derived stem cell factor.

Mast cell tryptase has been implicated in a wide variety of conditions associated with fibroproliferative tissue responses, including idiopathic bronchiolitis obliterans organizing pneumonia (BOOP), chronic inflammatory hepatobiliary disease, renal interstitial fibrosis, and male infertility. The role of tryptase in these conditions is supported by in vitro studies, which have demonstrated that mast cell tryptase can stimulate fibroblast proliferation through prostaglandin and COX2-mediated activation of protease-activated receptor 2 (PAR2).

Patients with HES and elevated serum tryptase levels, but not those with normal tryptase levels, demonstrated clinical and pathological evidence of tissue fibrosis, including endomyocardial fibrosis, restrictive pulmonary disease, and increased reticulin staining in the bone marrow, consistent with the hypothesis that mast cell tryptase, and not eosinophil products, are responsible for the tissue fibrosis seen in patients with the myeloproliferative form of HES.
In summary, we have described a subset of patients with a myeloproliferative form of idiopathic hypereosinophilic syndrome that is associated with elevated serum tryptase, mast cell dysplasia with a unique surface phenotype and poor prognosis. This clinical subtype appears to correlate with the presence of a recently described fusion tyrosine kinase, \textit{FIP1L1-PDGFR\alpha}, that is a therapeutic target of imatinib in HES \(^7\). Despite the fact that the laboratory findings in most of these patients fulfill the currently accepted diagnostic criteria for mastocytosis, HES with elevated serum tryptase levels appears to be a syndrome that is distinct from systemic mastocytosis with eosinophilia, suggesting that these criteria will need to be refined. Stimulation of mast cells by eosinophils to produce tryptase may explain the observed relationship between this form of HES, tissue fibrosis, and a decreased response to therapy directed at lowering the eosinophil response without an effect on mast cell proliferation. This hypothesis is strengthened by the observation that the response to imatinib in this subset of patients is characterized not only by a decrease in eosinophilia, but also by the disappearance of atypical mast cells, normalization of serum tryptase levels and resolution of myelofibrosis (data not shown). In conclusion, serum tryptase levels may be useful as a clinical marker of myeloproliferative HES, a predictor of imatinib-responsiveness and as a means to follow therapy in this subgroup of patients.

**Acknowledgments**

The authors would like to thank Barbara Foster for her assistance with the mast cell flow cytometry, Drs. Macdonald Horne, Barbara Karp, James Shelhamer, Maria Turner, and Paul Keiser who helped with the clinical characterization of the patients, Leigh Bernardino and Donna Jo McCloskey for their assistance with patient scheduling, the
many referring physicians and the study participants without whom this study would not have been possible.

SM-3 Y Purified bone RT-PCR followed by RFLP

*a bone marrow aspirate could not be obtained from this patient secondary to severe myelofibrosis
Elevated serum tryptase levels identify a subset of patients with a myeloproliferative variant of idiopathic hypereosinophilic syndrome associated with tissue fibrosis, poor prognosis, and imatinib responsiveness
