Interactions of *Aspergillus fumigatus* with Endothelial Cells: Internalization, Injury and Stimulation of Tissue Factor Activity

Running Head: *A. fumigatus* and Endothelial Cells

Abstract

Invasive aspergillosis causes significant mortality among patients with hematologic malignancies. This infection is characterized by vascular invasion and thrombosis. To study the pathogenesis of invasive aspergillosis, we investigated the interactions of *Aspergillus fumigatus* conidia and hyphae with endothelial cells *in vitro*. We found that both forms of the organism induced endothelial cell microfilament rearrangement and subsequent endocytosis. Conidia were endocytosed two-fold more avidly than hyphae, and endocytosis was independent of fungal viability. Endocytosed conidia and hyphae caused progressive endothelial cell injury after 4 hours of infection. Live conidia induced more endothelial cell injury than did live hyphae. However, endothelial cell injury caused by conidia was dependent on fungal viability, whereas injury caused by hyphae was not, indicating that conidia and hyphae injure endothelial cells by different mechanisms. Neither live nor killed conidia increased tissue factor activity of endothelial cells. In contrast, both live and killed hyphae stimulated significant endothelial cell tissue factor activity, as well as the expression of tissue factor antigen on the endothelial cell surface. These results suggest that angioinvasion and thrombosis caused by *A. fumigatus* hyphae *in vivo* may be due in part to endothelial cell invasion, induction of injury and stimulation of tissue factor activity.
Introduction

Invasive aspergillosis has become one of the leading causes of death among bone marrow transplant and leukemia patients. Even with current therapy, the mortality rate of invasive aspergillosis is 80 to 90% in immunocompromised patients.\textsuperscript{1} \textit{Aspergillus fumigatus} is responsible for 90% of invasive \textit{Aspergillus} infections.\textsuperscript{1} This ubiquitous mould releases numerous conidia into the atmosphere, which are small enough (2 to 3 µm in dia.) to reach the pulmonary alveoli after they are inhaled.\textsuperscript{2} Once the conidia reach the alveoli, they swell and germinate, producing hyphae that invade the pulmonary parenchyma. These hyphae have a marked tropism for blood vessels. A key finding in invasive aspergillosis is angioinvasion, which subsequently leads to thrombosis and tissue infarction.\textsuperscript{3-5} In immunocompromised hosts, invasion of the pulmonary vasculature can result in widespread hematogenous dissemination to organs such the brain, kidneys, heart and eyes.\textsuperscript{1,3}

During angioinvasion, \textit{A. fumigatus} hyphae interact with vascular endothelium. We hypothesize that this interaction plays an important role in the pathogenesis of invasive aspergillosis. Once the hyphae have entered the bloodstream, they must adhere to and penetrate the endothelial cell lining of the blood vessels to invade the deep tissues of the target organs.

In addition, the prominent thrombosis at sites of \textit{A. fumigatus} angioinvasion suggests that the organism stimulates endothelial cells to become prothrombotic. A major mechanism by which endothelial cells can promote intravascular thrombus formation is by expressing tissue factor, also known as thromboplastin or CD142.\textsuperscript{6-9} This 45 kDa transmembrane cell surface glycoprotein is expressed by endothelial cells, platelets and leukocytes. It is also present on endothelial microparticles.\textsuperscript{10,11} Tissue factor binds to factor VII, and forms a tissue factor-factor VIIa complex, which initiates the extrinsic coagulation cascade.\textsuperscript{7,9}
To study the pathogenesis of angioinvasion and thrombosis during invasive aspergillosis, we investigated the mechanisms by which *A. fumigatus* hyphae invade and injure vascular endothelial cells in vitro. We also examined whether these hyphae were able to stimulate endothelial cells to express tissue factor.

**Material and Methods**

**Reagents and antibodies**
Lipopolysaccharide (LPS) (*Escherichia coli* 0111.B4) was from List Biological Laboratories (Campbell, CA). Human factor VII and human factor X were from Enzyme Research Laboratories (South Bend, IN). Pefachrome® FXa and Russel viper venom were from Centerchem, Inc (Norwalk, CT). Alexa Fluor 488 phalloidin, Alexa Fluor 568 goat anti-rabbit IgG, and Slow Fade mounting medium were from Molecular Probes (Eugene, OR). Mouse anti-tissue factor monoclonal antibody, IgG1 (clone GMA-311) was from Green Mountain Antibodies (Burlington, VT). FITC conjugated goat anti-mouse IgG, cytochalasin D, thimerosal (2-[ethylmercuriomercurcapto] benzoic acid sodium salt) and bovine serum albumin (BSA) were from Sigma-Aldrich (St. Louis, MO). Fibronectin was from BD Biosciences (Bedford, MA). Medium 199 (M-199), gelatin, L-glutamine, penicillin, and streptomycin were from Gibco (Grand Island, N.Y.). Fetal bovine serum and bovine calf serum were from Gemini Bio-Products (Woodland, CA). Hank’s balanced salt solution was from (Irvine Scientific, Santa Clara, CA). Sabouraud dextrose agar, Sabouraud dextrose broth, and yeast nitrogen base broth were from Difco Laboratories (Detroit, MI).
Microorganisms

*Aspergillus fumigatus* strains H237 and AF293 were kind gifts of Dr. Judith Rhodes (University of Cincinnati) and Dr. Paul T. Magee (University of Minnesota), respectively. Strains AF2, AF7 and AF11 were generously supplied by Dr. Nancy Madinger (University of Colorado Health Sciences Center). *Candida albicans* SC5314 was obtained from Dr. William Fonzi (Georgetown University). All fungal strains used in these experiments were clinical isolates.

Growth and preparation of the organisms

The *A. fumigatus* strains were grown on Sabouraud agar for 7 days at 37°C. Their conidia were harvested by gently rinsing the plates with 0.1% Tween 80 in phosphate buffered saline, pH 7.4 (PBS) and then washed twice in PBS without Tween 80. Germ tubes were obtained by incubating the conidia in Sabouraud broth on gelatin coated Petri dishes for 5 to 6 hours at 37°C. Next, the medium above the germinated conidia was aspirated and the Petri dishes were washed twice with PBS. When necessary, the germ tubes were stored overnight at 4°C. The germ tubes were harvested from the dishes with a cell scraper. By microscopic examination, the majority of the organisms were single germ tubes, with a few small clumps containing 2-4 organisms. To obtain an even more homogeneous germ tube preparation, the suspension was gently sonicated for 10 seconds using a Branson Sonifier 450 (output level 2; Branson Ultrasonics, Danbury, CT). The *C. albicans* cells were grown overnight in yeast nitrogen base broth supplemented with 2% glucose (wt/vol) at 20°C on a rotating drum. All organisms were counted in a hemacytometer and adjusted to the desired concentration in tissue culture medium (M-199 medium containing 2 mM L-glutamine, penicillin and streptomycin, and supplemented with 10% fetal bovine serum and 10% bovine calf serum), prior to use. Conidia or germ tubes were killed by incubating them
in 0.02% thimerosal in PBS overnight at 4°C. This method of killing was used to preserve cellular integrity and minimize loss of cell wall components. Killing was verified by plating the organisms on Sabouraud agar. The killed organisms were rinsed extensively in PBS before use.

**Endothelial cells**

Endothelial cells were harvested from human umbilical veins by the method of Jaffe et al. The cells were grown in tissue culture medium. For use in the various assays, second or third passage endothelial cells were grown to confluency on a fibronectin matrix in 96-well or 24-well tissue culture plates (BD Biosciences, Bedford, MA) or on 12 mm dia. circular glass coverslips. All incubations were at 37°C in 5% CO₂.

**Endocytosis assay**

The number of *A. fumigatus* conidia and germ tubes internalized by the endothelial cells was determined by a modification of our previously described differential fluorescence assay. Briefly, endothelial cells grown on glass coverslips were infected with 6 x 10⁴ conidia or germ tubes of *A. fumigatus* H237 in tissue culture medium for 45 minutes. In some experiments, the microfilament inhibitor, cytochalasin D was added to the wells just before the organisms to achieve a final concentration of 70 nM. In these experiments, the control wells received an equal volume of the diluent (DMSO). At the end of the incubation period, the cells were fixed with 3% paraformaldehyde and then blocked overnight with 1% goat serum in PBS. The non-internalized microorganisms were stained by first incubating the infected monolayers with a 1:100 dilution of an anti-*A. fumigatus* polyclonal rabbit serum (kindly supplied by Dr. Jean-Phillipe Bouchara, Université D’Angers), followed by incubation with an Alexa fluor 568 (which
fluoresces red) goat anti-rabbit IgG (1 µg/ml) in PBS with 1% BSA. Next, the endothelial cells were permeabilized in 0.1% (vol/vol) Triton X-100 in PBS, after which both internalized and non-internalized organism were stained with 1% (vol/vol) Uvitex (which fluoresces blue).\textsuperscript{18} The coverslips were mounted inverted on a microscope slide with SlowFade, sealed with nail polish, and viewed under epifluorescence using filters specific for Alexa fluor 568 and Uvitex. In each high-powered microscopic field, the number of organism endocytosed by endothelial cells was determined by subtracting the number of non-internalized organisms (which fluoresced red) from the total number of organism (which fluoresced blue). At least 100 organisms were counted on each coverslip, and all experiments were performed in duplicate on at least three separate occasions. The results were expressed as both the number of endocytosed organisms per high power field (HPF).

**Fluorescent microscopy**

For all fluorescence microscopy experiments, the endothelial cells were grown to confluency on glass coverslips as described above and incubated with $3 \times 10^5$ *A. fumigatus* cells. To visualize the endothelial cell microfilaments, the endothelial cells were fixed with 3.7% formaldehyde, permeabilized with 0.1% (vol/vol) Triton X-100 in PBS for 5 minutes and then blocked with 1% BSA in PBS for 30 minutes. The microfilaments were stained with Alexa Fluor 488 phalloidin following the manufacturer’s instructions.

To detect tissue factor expression, the endothelial cell monolayers were fixed in 3.7% formaldehyde and blocked with 1% goat serum as above. Next, the cells were incubated with 10 µg/ml of a mouse anti-tissue factor monoclonal antibody for 1 hour, followed by a FITC conjugated goat anti-mouse IgG at a 1:100 dilution. In all experiments, the coverslips were
mounted inverted onto slides and viewed by confocal microscopy with a Leica TCS SP2 microscope (Leica Microsystems, Inc., Bannockburn, IL). The confocal images were constructed by stacking 0.5 micron optical sections acquired along the z-axis.

**Endothelial cell injury**

The amount of endothelial cell injury induced by conidia and hyphae was quantified by the release of $^{51}$Cr as previously described.$^{15,19,20}$ Briefly, endothelial cells were grown to confluence in 96-well plates containing detachable wells. The cells were incubated overnight with 1 µCi of Na$_2$$^{51}$CrO$_4$ (ICN Biomedicals, Irvine, CA) per well. The following day, the unincorporated tracer was aspirated and the wells were rinsed twice with pre-warmed Hank’s balanced salt solution. Next, endothelial cells were incubated with $10^5$ organisms per well in 100 µl of tissue culture medium. After incubation, the upper 50% of the medium was aspirated from each well and then the wells were manually detached from one another. The amount of $^{51}$Cr in the aspirates and in the wells was determined by gamma counting. To measure the spontaneous release of $^{51}$Cr, uninfected endothelial cells exposed to medium alone were processed in parallel. In experiments with killed organisms, the equivalent volume of the supernatant from the last thimerosal wash was added to the endothelial cells to control for the release of any toxic material as a result of the thimerosal treatment.

The results were adjusted for the volume of medium removed from the wells and the percent specific release of $^{51}$Cr was calculated using the following formula: (experimental release – spontaneous release)/(total incorporation – spontaneous release) x 100. Each experiment was performed in triplicate at least three different times. After 8 hours of incubation in medium alone, the average spontaneous release of $^{51}$Cr was 24% ± 4%. To determine the maximal
release of $^{51}$Cr by the endothelial cells, the cells were lysed by the addition of 0.5% Triton X-100 to the medium. Using the above formula, the average release of $^{51}$Cr in these cells was 85% ± 5%. This specific release of $^{51}$Cr was essentially the same when Triton X-100 was added to either endothelial cells incubated with medium alone or infected with *A. fumigatus* for 8 hours.

In preliminary experiments, we incubated *A. fumigatus* hyphae were incubated with $^{51}$Cr under the same labeling conditions that were used for the endothelial cells. These hyphae incorporated minimal $^{51}$Cr (data not shown). Therefore, *A. fumigatus* cells were unlikely to take up a significant amount of $^{51}$Cr released by the injured endothelial cells.

For the experiments to determine if soluble factors released by *A. fumigatus* could injure the endothelial cells, a modification of the above protocol was used. The endothelial cells were seeded on 24-well tissue culture plates and cell culture inserts (pore size 0.4 µm; BD Biosciences) were placed in each well, suspended approximately 1 mm above endothelial cells. Next, $6 \times 10^5$ conidia were added to the endothelial cells, the cell culture inserts or both. At the end of the incubation, the medium was gently removed and the endothelial cells were lysed by the addition of 0.5 ml of 6 N NaOH. The lysed cells were aspirated and the wells were rinsed with 0.5 ml of RadiacWash (Atomic Products Inc., Shirley, N.Y.). These rinses were added to the cell lysate. The $^{51}$Cr activity was determined in the medium and in the cell lysates and the damage calculated as described above.

**Tissue factor assay**

The expression of tissue factor by the endothelial cells was measured by a colorimetric assay.$^{21}$ All reagents and solutions used in these experiments were endotoxin free. Briefly, confluent endothelial cells in 96-well plates were washed once with warm PBS and incubated with $10^5$ A.
*A. fumigatus* or *C. albicans* cells for 2, 4, 8 and 16 hours. Control wells with *A. fumigatus* alone were run in parallel. As a positive control, endothelial cells were stimulated with 1 ng LPS per ml. At each time point, the medium above the cells was gently aspirated. Next, the endothelial cells were incubated with 50 µl of 10 nM factor VII in buffer A (10 mM HEPES, 137 mM NaCl, 4 mM KCl, 11 mM glucose, 25 mM CaCl₂ and 5 mg/ml BSA, pH 7.4) for 20 min at 37°C under rotation at 200 rpm to allow formation of the tissue factor-factor VII-Ca²⁺ complex. Next, 10 µl containing 6 U of factor X per ml of buffer A was added to each well. After a 5-minute incubation at 37°C, a 25 µl sample was removed from each well and added to 25 µl of 125 mM triethanolamine, 250 mM NaCl, 50 mM EDTA, 25 µM BSA , pH 8.2 in a 96-well ELISA plate, at 4°C to stop the formation of factor Xa. The plate was warmed to 37°C and 10 µl of a 5 mM solution of the substrate Pefachrome FXa in 100 mM triethanolamine, 200 mM NaCl, 5 mM CaCl₂, pH 8.2 was added to each well. The reaction was developed for 5 minutes, stopped with 50 µl of 50% acetic acid and the optical density determined at 405 nm in an ELISA plate reader (Dynex Technologies, Middlesex, UK). The kinetic conditions and the linearity of FXa formation were determined by time course experiments using factor X that had been fully activated with Russell viper venom. The data were expressed as the stimulation index, which was the fold increase in tissue factor expression relative to the basal level of tissue factor expressed by endothelial cells incubated with tissue culture medium alone. Each experiment was performed in duplicate and repeated at least three times.

**Statistical analysis**

Differences among the experimental groups were assessed using analysis of variance with the Bonferroni correction for multiple comparisons. *P* values of ≤ 0.05 were considered significant.
Results

Interactions of *A. fumigatus* conidia, germ tubes, and hyphae with endothelial cells

We first examined the interactions of *A. fumigatus* conidia, germ tubes, and hyphae with endothelial cells in vitro using phase contrast microscopy. When the organisms were added to the endothelial cells as resting conidia, they settled onto the cells within 30 minutes (Figure 1A), and began to swell by 3 hours (Figure 1B). Some of these swollen conidia were visible in the perinuclear position of the endothelial cells, suggesting that they had been internalized (Figure 1B). After 8 hours of infection, the swollen conidia became polarized and began to germinate. Both pear shaped organisms and a few germ tubes were visible at this time point (Figure 1C).

![Figure 1. Interactions *A. fumigatus* conidia and germ tubes with endothelial cells. Photomicrographs of endothelial cell monolayers infected with *A. fumigatus* H237 conidia (A to C) and germ tubes (D to F) after 30 minutes (A and D), 3 hours (B and E), and 8 hours (C and F). Original magnification 20X. Arrows indicate the organisms.](image-url)
During invasive aspergillosis, it is highly probable that the inhaled *A. fumigatus* conidia germinate and form hyphae before they come in contact with the vascular endothelium. Therefore, we examined the endothelial cell interactions of organisms that had been pre-germinated prior to being added to the endothelial cell monolayers. These germ tubes rapidly settled onto the monolayer (Figure 1D) and progressive elongated so that a hyphal mat was formed by 3 hours (Figure 1E). After 8 hours of infection, this hyphal mat had completely covered the endothelial cells (Figure 1F).

Conidia and hyphae induce rearrangement of endothelial cell microfilaments and subsequent endocytosis

We compared the endothelial cell uptake of *A. fumigatus* conidia and germ tubes using a differential fluorescence assay. After 45 minutes, two-fold more conidia than germ tubes were internalized by the endothelial cells (Figure 2). Addition of cytochalasin D, a microfilament

![Figure 2. Endocytosis of *A. fumigatus* by endothelial cells. *A. fumigatus* H237 conidia and germ tubes were incubated with endothelial cells for 45 minutes in the presence or absence of the microfilament inhibitor, cytochalasin D. The number of organisms endocytosed by the endothelial cells was determined by a differential fluorescence assay. Results are mean ± standard deviation of three experiments. *p < 0.001 compared to cells without cytochalasin D; §p < 0.05 compared to conidia.](image-url)
inhibitor, reduced the uptake of conidia and germ tubes by 60% and 80%, respectively. The inhibitory effect of cytochalasin D on the internalization of the organisms indicates that both forms of \textit{A. fumigatus} invade endothelial cells by inducing their own endocytosis.

To visualize the involvement of microfilaments in the endocytosis of \textit{A. fumigatus}, the infected endothelial cells were stained with Alexa Fluor 488 phalloidin and viewed by confocal microscopy. Endocytosis of both conidia and hyphae was accompanied by the polymerization of endothelial cell actin around the organisms (Figure 3). Some endothelial cells endocytosed multiple organisms, particularly conidia. In some cases, two endothelial cells could be observed endocytosing different portions of the same hyphus. After endocytosis was complete, the

Figure 3. Confocal microscopy of actin filaments surrounding endocytosed organisms. Endothelial cells were incubated for 45 minutes with \textit{A. fumigatus} H237 conidia (A, B) or germ tubes (C, D), and then stained for filamentous actin. (A, C) Confocal images of the filamentous actin. (B, D) Differential interference contrast images of the same microscopic fields as A and C, respectively. Arrows indicate endothelial cell actin polymerizing around the organisms (A, C) and the organisms themselves (B, D). Original magnification 1000X.
internalized organisms were no longer surrounded by polymerized actin. A similar pattern of actin polymerization was observed when the endothelial cells were incubated with killed organisms (data not shown), indicating that the endocytosis of *A. fumigatus* is independent of the viability of the organism.

**A. fumigatus conidia and germ tubes injure endothelial cells by different mechanisms**

It is known that *C. albicans* and *Cryptococcus neoformans*, which interact with endothelial cells during hematogenous dissemination, cause significant endothelial cell injury in vitro.\(^{19,22}\) We therefore evaluated the extent of endothelial cell injury caused by *A. fumigatus* conidia and germ tubes. When the endothelial cells were infected with resting conidia, cellular injury became detectable after 4 hours (Figure 4A). At this time, the conidia had become swollen, but had not yet germinated. The extent of endothelial cell injury caused by *A. fumigatus* increased progressively with time as the swollen conidia subsequently germinated (Figures 1 and 4A).

To investigate whether different strains of *A. fumigatus* varied in their capacity to injure endothelial cells, we tested five clinical isolates of *A. fumigatus* in the endothelial cell injury assay. All five isolates caused a similar amount of endothelial cell injury after 8 hours of infection (Figure 4B).

Next, we compared the extent of endothelial cell injury caused by live and killed conidia and germ tubes. Live conidia of *A. fumigatus* caused greater endothelial cell injury than did live germ tubes after 8 hours of infection (Figure 4C). Fungal viability was important for endothelial cell injury by conidia, as killed conidia induced minimal injury after 8 hours (Figure 4C) or even after 16 hours of incubation (data not shown). Surprisingly, endothelial cell injury caused by germ tubes was independent of fungal viability, because killed germ tubes induced the same
Figure 4. Endothelial cell injury induced by *A. fumigatus*. (A) Time course of injury. Endothelial cells were incubated with conidia of *A. fumigatus* H237 for the indicated times and the extent of endothelial cell injury was determined by the specific release of $^{51}$Cr as described in Methods. (B) Extent of injury caused by different clinical isolates. Endothelial cells were infected with conidia of the indicated clinical isolates of *A. fumigatus* for 8 hours, after which endothelial cell injury was measured. (C) Comparison of endothelial cell injury caused by live and thimerosal-killed conidia and hyphae of *A. fumigatus* H237 after 8 hours. Results are means ± standard deviation of at least three independent experiments. *p < 0.001 versus uninfected control wells; §p > 0.05 versus live organisms; †p < 0.001 versus conidia.

extent of endothelial cell injury as did live germ tubes (Figure 4C). These results suggest that *A. fumigatus* conidia and germ tubes injure endothelial cells by different mechanisms.
Endothelial cell injury by *A. fumigatus* requires endocytosis of the organism

To determine if direct contact is required for *A. fumigatus* to injure endothelial cells, we interposed cell culture inserts between the endothelial cells and live conidia. This procedure completely abolished endothelial cell injury after 8 hours of infection (Figure 5A) and 16 hours (data not shown).

Figure 5. Effects of cell contact and endocytosis on endothelial cell injury caused by *A. fumigatus*. (A) Extent of endothelial cell injury caused by conidia of *A. fumigatus* H237 that were added directly onto endothelial cells monolayers in a 24-well plate and/or into 0.4 µm cell culture inserts suspended above the monolayers. (B) Extent of endothelial cell injury caused by *A. fumigatus* H237 conidia in the presence of the indicated concentrations of the microfilament inhibitor, cytochalasin D. Endothelial cell injury was measured after 8 hours of infection and the results are the mean ± standard deviation of at least three independent experiments. *p < 0.001 compared to control.
Next, we infected the endothelial cells in the presence of cytochalasin D to determine whether endocytosis of *A. fumigatus* is required for endothelial injury to occur. We found that 70 nM cytochalasin D caused an 89% reduction in endothelial cell injury caused by *A. fumigatus* (Figure 5B). This concentration of cytochalasin D had no visible effect on the *A. fumigatus* cells and caused less than 5% specific release of $^{51}$Cr when added to uninfected endothelial cells (data not shown).

*A. fumigatus* hyphae induces tissue factor expression

In invasive aspergillosis, angioinvasion is accompanied by thrombus formation. One mechanism by which *A. fumigatus* can induce intravascular thrombosis is by inducing tissue factor expression by endothelial cells. We therefore investigated whether *A. fumigatus* conidia and hyphae stimulate endothelial cell tissue factor activity. We found that the basal level of tissue factor activity expressed by uninfected endothelial cells was low, although this level varied with the endothelial cell donor (range 0.78 to 2.34 factor Xa units). Incubation of endothelial cells with live or killed conidia for up to 16 hours resulted in minimal increase in tissue factor activity (Figure 6). In contrast, germ tubes stimulated a progressive increase in tissue factor activity, starting at 4 hours of incubation. Both live and killed germ tubes induced similar levels of tissue factor activity.

In these experiments, the endothelial cells were stimulated with LPS as a positive control. The time course of LPS stimulation of endothelial cell tissue factor activity was similar to that induced by *A. fumigatus* germ tubes, although LPS induced a greater response than did the germ tubes at 16 hours (Figure 6 inset).
To determine if the induction of tissue factor activity by *A. fumigatus* represents a generalized response to endothelial cell injury, we tested whether *C. albicans* could induce endothelial cell tissue factor activity. We have shown previously that this organism causes extensive endothelial cell injury.\textsuperscript{15,19,20} Interestingly, endothelial cells infected with *C. albicans* expressed only basal levels of tissue factor activity at all time points tested (data not shown).

We also examined whether *A. fumigatus* germ tubes themselves express tissue factor activity by testing wells containing organisms in the absence of endothelial cells. These wells had no activity (data not shown). Finally, we omitted factor VII from the assay for tissue factor activity to determine if substances such as proteases released by *A. fumigatus* could mimic the activity of the tissue factor-factor VII complex and convert factor X to factor Xa. We found that in the absence of factor VII, no factor Xa was formed by endothelial cells infected with *A.
fumigatus (data not shown). Collectively, these results indicate that the increased tissue factor activity associated with endothelial cells infected with A. fumigatus is due to the endothelial cell response to the organism, rather than factors produced by the organism itself.

To verify that the enhanced tissue factor activity was due to the increased expression of tissue factor on the endothelial cell surface, we infected endothelial cells with A. fumigatus germ tubes for 8 hours and then detected tissue factor expression by indirect immunofluorescence. As predicted by the results of the tissue factor activity assay, there was low expression of tissue factor on the surface of uninfected endothelial cells (Figure 7A), whereas endothelial cells

![Figure 7. Expression of tissue factor on the surface of infected endothelial cells.](image)

Endothelial cells monolayers grown on glass coverslips were incubated for 8 hours with tissue culture medium (A), LPS (B), or germ tubes of A. fumigatus (C, D). The expression of tissue factor on the endothelial cell surface was detected by confocal microscopy using an anti-tissue factor monoclonal antibody (A, C). Panel D shows the differential interference contrast image corresponding to the same field as panel C. Results are representative of three independent experiments. Original magnification 400X.
infected with *A. fumigatus* expressed high levels of tissue factor on their surface (Figure 7C). Interestingly, tissue factor was expressed over the entire luminal surface of the infected endothelial cells, not just at points of hyphal contact.

**Discussion**

During angioinvasion by *A. fumigatus* in both experimental animal models and humans, only hyphal phase organisms are visible in the tissues.\(^2,4,5,24\) This finding indicates that the hyphus is the principal form of the organism that interacts with endothelial cells and suggests that hyphae have a unique capacity to survive and proliferate within the host. We therefore compared the interactions of *A. fumigatus* conidia and hyphae with endothelial cells.

We found that while both forms of *A. fumigatus* were internalized by endothelial cells via an actin-dependent mechanism, conidia were endocytosed more avidly than were hyphae. This difference in the rate of endocytosis between the two morphologies may be due to the difference in their size. In addition, it is possible that conidia and hyphae possess different numbers and/or types of endothelial cell binding proteins on their surface. Although the endocytosis of *A. fumigatus* conidia by endothelial cells in vitro has been described by others,\(^25,26\) the endocytosis of *A. fumigatus* hyphae has not been reported previously. In autopsy studies, *A. fumigatus* hyphae can clearly be seen to cross the wall of the blood vessels.\(^4,5,23,24\) However, to our knowledge, the electron microscopy studies necessary to observe endothelial cell invasion by the hyphae not been performed.

*A. fumigatus* conidia and hyphae also differed in their capacity to injure endothelial cells. Organisms that were added to endothelial cells as conidia caused significantly more endothelial cell injury after 8 hours than did organisms that were added to endothelial cells as germ tubes.
This finding was surprising because the conidia had just begun to germinate after 8 hours of incubation with the endothelial cells (Figure 1C). In contrast, the pregerminated organisms had almost completely covered the endothelial cells with a hyphal mat by this time point (Figure 1F). Thus, there was much greater contact between the endothelial cells and the A. fumigatus cells when the organisms were pregerminated before being added to the monolayers. It is possible that conidia caused greater injury because more of them were endocytosed by the endothelial cells. It is also possible that contact with the endothelial cells induced conidia to synthesize greater amounts of injurious factors than were synthesized by organisms that were pregerminated in the absence of endothelial cells.

Another important finding was that although killed conidia caused no detectable endothelial cell injury, killed germ tubes caused as much injury as did live germ tubes. One explanation for the lack of endothelial cell injury caused by killed, resting conidia is that they must begin to swell or germinate before they can cause endothelial cell injury. The finding that killed germ tubes injured endothelial cells suggests that a factor associated with the cell surface of the germ tubes causes endothelial cell injury when the germ tubes are endocytosed. In support of this conclusion, we have found that cell wall extracts of A. fumigatus hyphae can also injure endothelial cells (Lopes-Bezerra and Filler, unpublished data).

By interposing filter inserts between A. fumigatus and the endothelial cells, we determined that direct contact between the organisms and endothelial cells appears to be necessary for endothelial cell damage to be induced under these culture conditions. Moreover, the finding that inhibiting endocytosis of the organism with cytochalasin D blocked endothelial cell injury indicates that endocytosis is an additional prerequisite for the induction of endothelial cell injury. A. fumigatus is known to secrete a variety of lytic enzymes including proteases and
phospholipases. It is possible that these secreted enzymes are most active when they achieve high concentrations in the endocytic vacuole of the endothelial cell. As mentioned previously, it is also likely that the hyphal cell wall itself is toxic to endothelial cells.

To investigate potential mechanisms by which A. fumigatus causes thrombosis at sites of angioinvasion, we examined whether this organism could induce endothelial cells to express tissue factor activity. We found that A. fumigatus hyphae, but not conidia stimulated endothelial cells to express factor activity. This finding again indicates that A. fumigatus conidia and hyphae interact differently with endothelial cells. Two lines of evidence demonstrate that the increase in tissue factor activity was due to the endothelial cells rather than the A. fumigatus. First, neither live nor killed A. fumigatus hyphae had any detectable tissue factor activity in the absence of endothelial cells. Furthermore, endothelial cells exposed to killed A. fumigatus hyphae expressed similar amounts of tissue factor activity as did endothelial cells exposed to live hyphae. Second, tissue factor antigen was detectable on the surface of the infected endothelial cells, but not on A. fumigatus hyphae.

C. albicans is another angioinvasive fungus and its interactions with endothelial cells in vitro have been investigated extensively. This organism is similar to A. fumigatus in that both live and killed hyphae are endocytosed by endothelial cells and this process can be inhibited by cytochalasin D. However, a major difference between the two organisms is that A. fumigatus conidia are endocytosed by endothelial cells more avidly than hyphae, whereas C. albicans hyphae are endocytosed more avidly than blastoconidia. There are also significant differences in endothelial cell injury caused by A. fumigatus and C. albicans. Unlike A. fumigatus conidia, C. albicans blastoconidia do not cause detectable endothelial cell injury. Furthermore, although killed A. fumigatus hyphae cause significant endothelial cell injury, killed
C. albicans hyphae do not.\textsuperscript{19} Therefore, A. fumigatus and C. albicans likely injure endothelial cells by different mechanisms.

We also found that C. albicans did not stimulate endothelial cell tissue factor activity. This result was particularly interesting because C. albicans is known to stimulate multiple endothelial cell responses including the expression of leukocyte adhesion molecules, and secretion of pro-inflammatory cytokines and prostaglandins.\textsuperscript{20,29-31} The difference in the ability of A. fumigatus and C. albicans to induce a prothrombotic state in endothelial cells in vitro parallels the histopathology of infections caused by these organisms in vivo. Invasive aspergillosis is characterized by extensive intravascular thrombosis at foci of infection,\textsuperscript{3-5,23} whereas thrombosis is not a prominent feature of disseminated candidiasis.\textsuperscript{32,33}

Other microorganisms, such as Staphylococcus aureus and Neisseria meningitidis are known to stimulate endothelial cells to express tissue factor in vitro.\textsuperscript{34-36} It is likely that stimulation of endothelial cell tissue factor expression contributes to formation of vegetations during staphylococcal endocarditis and to disseminated intravascular coagulation during meningococcemia.\textsuperscript{34,37} Other microbial pathogens, such as cytomegalovirus, Chlamydia pneumoniae, Streptococcus sanguis, and Plasmodium falciparum may also induce tissue factor expression at sites of infection.\textsuperscript{38-40} However, these organisms induce tissue factor expression by activating monocytes, which can express tissue factor by themselves, as well as stimulate endothelial cells to express tissue factor. Whether monocytes augment A. fumigatus tissue factor endothelial cell tissue factor expression has not yet been determined.

In summary, A. fumigatus hyphae invade endothelial cells in vitro by inducing their own endocytosis. The internalized organisms then injure the endothelial cells and stimulate them to express tissue factor. This process provides a potential mechanism for the vascular invasion and
thrombosis that characterize invasive aspergillosis. Studies to examine the mechanism by which
A. fumigatus hyphae induce tissue factor expression and to confirm tissue factor expression at
foci of invasive aspergillosis in vivo are currently in progress.

Acknowledgements

We thank the perinatal nurses at Harbor-UCLA Medical Center for collecting the umbilical
cords, Quynh Phan for help with tissue culture, and Dr. Matthew J. Schibler at the Brain
Research Institute at UCLA for expert assistance with confocal microscopy.
