Primary cutaneous lymphomas are currently classified by the EORTC classification or the WHO classification, but both systems have shortcomings. In particular, differences in the classification of cutaneous T-cell lymphomas other than mycosis fungoides, Sézary syndrome and the group of primary cutaneous CD30-positive lymphoproliferative disorders and the classification and terminology of different types of cutaneous B-cell lymphomas have resulted in considerable debate and confusion. During recent consensus meetings representatives of both systems reached agreement on a new classification, which is now called the WHO-EORTC classification. In this paper we describe the characteristic features of the different primary cutaneous lymphomas and other hematologic neoplasms frequently presenting in the skin, and discuss differences with the previous classification schemes. In addition, the relative frequency and survival data of 1905 patients with primary cutaneous lymphomas derived from Dutch and Austrian registries for primary cutaneous lymphomas are presented to illustrate the clinical significance of this new classification.
Introduction

A variety of T-and B-cell neoplasms can involve the skin, either primarily or secondarily. The term ‘primary cutaneous lymphoma’ refers to cutaneous T-cell lymphomas (CTCL) and cutaneous B-cell lymphomas (CBCL) that present in the skin with no evidence of extracutaneous disease at the time of diagnosis. After the gastrointestinal tract, the skin is the second most common site of extranodal non-Hodgkin lymphoma with an estimated annual incidence of 1/100,000.1 Primary cutaneous lymphomas often have a completely different clinical behavior and prognosis from histologically similar systemic lymphomas, which may involve the skin secondarily, and therefore require different types of treatment. For that reason, recent classification systems for non-Hodgkin lymphomas such as the European Organization for Research and Treatment of Cancer (EORTC) classification for primary cutaneous lymphomas and the World Health Organization (WHO) classification for tumours of haematopoietic and lymphoid tissues included primary cutaneous lymphomas as separate entities.2,3 In the EORTC classification distinction was made between primary cutaneous lymphomas with an indolent, intermediate or aggressive clinical behavior. The clinical validity of this classification has been validated by several large studies including follow-up data of more than 1300 patients with a primary cutaneous lymphoma.2,4,5 Whereas there was consensus between the EORTC and WHO classifications on the classification of most types of CTCL, remaining differences between the two classification systems, in particular the controversy on the definition and terminology of the different types of CBCL, has resulted in considerable debate and confusion.6-9 During consensus meetings in Lyon (September 2003) and Zurich (January 2004) these differences were resolved by representatives of both classification systems, and a consensus classification was developed (Table 1). In this report we present the new WHO-EORTC classification for cutaneous lymphomas. This review will focus on primary cutaneous lymphomas and a few other conditions that frequently first present in the skin, such as CD4+/CD56+ hematodermic neoplasm (formerly also known as blastic NK cell lymphoma) and adult T-cell leukemia/lymphoma. Other neoplasms that may also first present in the skin in a minority of cases, such as precursor-B lymphoblastic leukemia/lymphoma and acute myeloid leukemia, and secondary cutaneous manifestations of systemic lymphomas are not discussed, but will be included in the monograph to be published in the WHO Blue Book series in 2005. After a discussion of the two most controversial groups of cutaneous lymphomas that were defined differently in the original EORTC and WHO classification schemes, the main features of the different types of primary cutaneous lymphoma are presented. In Table 2 the relative frequency and survival of 1905 patients with primary cutaneous lymphomas derived from Dutch and Austrian cutaneous lymphoma registries are presented, to illustrate the clinical significance of the WHO-EORTC classification.
The classification of this remaining group of CTCL is difficult and confusing, which is not surprising given the heterogeneity and rarity of these tumors. Together, they constitute less than 10% of all CTCL. With few exceptions, these lymphomas are clinically aggressive and in most cases systemic chemotherapy is required. In the EORTC classification, most of these lymphomas were grouped as primary cutaneous CD30-negative large T-cell lymphoma or in the provisional group of primary cutaneous small/medium-sized pleomorphic CTCL (Table 2). Distinction between these two categories, which is based on the presence of more or less than 30% large neoplastic T-cells, was considered useful because several studies demonstrated a significant difference in survival between these two groups. Recent studies suggest, however, that this favorable prognosis is restricted to small/medium-sized pleomorphic CTCL with a CD4+ T-cell phenotype, in particular those that present with localized disease, in contrast to those with a CD8+ T-cell phenotype. Moreover, the EORTC category of CD30-negative large cell CTCL has become quite heterogeneous through the recognition of new diagnostic categories, such as subcutaneous panniculitis-like T-cell lymphoma (SPTL), extranodal NK/T-cell lymphoma, nasal type, CD4+/CD56+ hematodermic neoplasm (blastic NK cell lymphoma), aggressive epidermotropic CD8-positive CTCL and cutaneous gamma/delta T-cell lymphoma. In the WHO classification, SPTL, nasal type NK/T-cell lymphoma and blastic NK cell lymphoma were included as separate entities, whereas the other entities were part of the broad category of peripheral T-cell lymphoma (PTL), unspecified.

In the WHO-EORTC classification, extranodal NK/T-cell lymphoma, nasal type and CD4+/CD56+ hematodermic neoplasm (blastic NK cell lymphoma), are defined as separate entities. Recent studies showed both clinical, histological and immunophenotypical differences between cases of SPTL with an α/β T-cell phenotype and those with a γ/δ T-cell phenotype, suggesting that these may represent different entities. Whereas SPTL with an α/β T-cell phenotype are homogeneous with a rather indolent clinical behaviour in many patients, SPTLCL with a γ/δ T-cell phenotype overlap with other types of γ/δ-positive T/NK-cell lymphoma and invariably run a very aggressive clinical course. We therefore suggest that the term SPTL be restricted for SPTL with an α/β T-cell phenotype. Recent studies have suggested that some disorders can be separated out as provisional entities from the broad group of PTL, unspecified, in the WHO classification. These include aggressive epidermotropic CD8+ CTCL, cutaneous gamma-delta T-cell lymphoma (including cases formerly diagnosed as SPTL with a gamma/delta phenotype) and primary cutaneous small-medium CD4+ T-cell lymphoma. In the WHO-EORTC classification the term PTL, unspecified, is maintained for remaining cases that do not fit into either of these provisional entities.
Primary cutaneous follicle center cell lymphoma and primary cutaneous diffuse large B-cell lymphoma

In recent years, the EORTC categories of primary cutaneous follicle center cell lymphoma (PCFCCL) and primary cutaneous large B-cell lymphoma of the leg (PCLBCL-leg) have been the subject of much debate. The term PCFCCL was introduced in 1987 as a term encompassing cutaneous lymphomas that were composed of cells with the morphology of follicle center cells, i.e. centroblasts and (large) centrocytes, and that were classified as either centroblastic/centrocytic or centroblastic according to criteria of the Kiel classification. Whereas small and early lesions may show both small and large neoplastic B-cells and many admixed T-cells, and may have a partly follicular growth pattern, tumorous lesions generally show a predominance of large B-cells, particularly large cleaved or multilobated cells, and less frequently a predominance of typical centroblasts and immunoblasts. In contrast to nodal follicular lymphomas, PCFCCL do generally not express bcl-2 and are not typically associated with the t(14;18) translocation. Clinically, most patients present with localized skin lesions on the head or trunk and, irrespective of the histologic subclassification on the basis of growth pattern or number of blast cells, are highly responsive to radiotherapy and have an excellent prognosis.

The WHO classification approached these lesions from a different perspective. PCFCCL with a partly follicular growth pattern were included as a variant of follicular lymphoma and designated cutaneous follicle center lymphoma, while cases with a diffuse growth pattern and a predominance of large centrocytes or centroblasts were generally classified as diffuse large B-cell lymphoma. The designation of this latter group as diffuse large B-cell lymphoma was controversial, since it could lead to overtreatment with multiagent chemotherapy rather than radiotherapy.

PCLBCL-leg was initially recognized as a subgroup of PCFCCL with a somewhat different histology and a more unfavorable prognosis. In the EORTC classification it was included as a separate subgroup. PCLBCL-leg particularly affects elderly people, has a higher relapse rate and a more unfavorable prognosis than PCFCCL with a diffuse large B-cell morphology. Histologically, they have a predominance of centroblasts and immunoblasts rather than large centrocytes, and consistently strongly express bcl-2 protein. Although delineation of this subgroup based on site has been criticized, recent clinicopathologic and genetic studies further support that PCFCCL and PCLBCL-leg are distinct groups of CBCL.

During the consensus meeting in Zurich, histologic slides of a large number of PCFCCL and PCLBCL-leg were reviewed, together with the immunophenotype and clinical data. It was recognized that PCFCCL as defined in the EORTC classification indeed form a spectrum of disease that includes cases with a follicular, a follicular and diffuse and a diffuse growth pattern, and a range of cellular composition from predominantly small centrocytes to a predominance of large centrocytes with variable numbers of admixed centroblasts and immunoblasts. This entity will further be referred to as primary cutaneous follicle center lymphoma (PCFCL). The group of PCLBCL-leg was also recognized as a separate entity. According to the results of a recent multi-center study, it is also clear that cases
with a similar morphology (predominance or cohesive sheets of centroblasts and immunoblasts), immunophenotype (strong expression of bcl-2 and Mum-1/IRF4) and prognosis may arise at sites other than the leg.\(^4^2\) In the WHO-EORTC classification the term\(\text{PCLBCL, leg type}\) is proposed for both lesions on the legs and similar lesions at other skin sites. In addition, the term\(\text{PCLBCL, other}\) is introduced for rare cases of PCLBCL not belonging to the group of PCLBCL, leg type or PCFCL with a diffuse infiltration of large centrocytes.

**CUTANEOUS T-CELL LYMPHOMA**

**MYCOSIS FUNGOIDES**

**Definition**

Mycosis fungoides (MF) is a commonly epidermotropic CTCL characterized by a proliferation of small to medium-sized T-lymphocytes with cerebriform nuclei. The term MF should be used only for the classical ‘Alibert-Bazin’ type characterized by the evolution of patches, plaques and tumors, or for variants showing a similar clinical course. MF is the most common type of CTCL and accounts for almost 50% of all primary cutaneous lymphomas (Table 2).

**Clinical features**

MF typically affects older adults (median age at diagnosis: 55-60 years; male to female ratio: 1.6-2.0:1), but may occur in children and adolescents.\(^4^7\)\(^-\)\(^5^0\) MF has an indolent clinical course with slow progression over years or sometimes decades, from patches to more infiltrated plaques and eventually tumors (Fig. 1A). In some patients, lymph node and visceral organs may become involved in the later stages of the disease. The initial skin lesions have a predilection for the buttocks and other sun-protected areas. Patients with tumor stage MF characteristically show a combination of patches, plaques and tumors, which often show ulceration. If only tumors are present, without preceding or concurrent patches or plaques, a diagnosis of MF is highly unlikely and another type of CTCL should be considered.

**Histopathology**

Early patch lesions in MF show superficial band-like or lichenoid infiltrates, mainly consisting of lymphocytes and histiocytes. Atypical cells with small to medium-sized, highly indented (cerebriform) and sometimes hyperchromatic nuclei are few, and mostly confined to the epidermis (epidermotropism). They characteristically colonize the basal layer of the epidermis either as single often haloed cells or in a linear configuration.\(^5^1\) In typical plaques, epidermotropism is generally more pronounced than in the patches (Fig.
The presence of intraepidermal collections of atypical cells (Pautrier’s microabscesses) is a highly characteristic feature, but is observed in only a minority of cases. With progression to tumor stage, the dermal infiltrates become more diffuse and epidermotropism may be lost. The tumor cells increase in number and size, showing variable proportions of small, medium-sized to large cerebriform cells, blast cells with prominent nuclei and intermediate forms. Transformation to a diffuse large cell lymphoma that may be either CD30-negative or CD30-positive may occur and is often associated with a poor prognosis.

**Immunophenotype**

The neoplastic cells in MF have a mature CD3+, CD4+, CD45RO+, CD8- memory T-cell phenotype. In rare cases of otherwise classical MF a CD4-, CD8+ mature T-cell phenotype may be seen. Such cases have the same clinical behavior and prognosis as CD4+ cases, and should not be considered separately. Demonstration of an aberrant phenotype (eg. loss of pan-T cell antigens such as CD2, CD3 and CD5) is often seen and is an important adjunct in the diagnosis of MF. Expression of cytotoxic proteins (TIA-1, granzyme B) by the neoplastic CD4+ T-cells has been detected in 10% of MF plaques, but is much more common in tumors showing blastic transformation.

**Genetic features**

Clonal T-cell receptor gene rearrangements are detected in most cases. Many structural and numerical chromosomal abnormalities have been described, in particular in the advanced stages of MF, but recurrent, MF-specific chromosomal translocations have not been identified. Chromosomal loss at 10q and abnormalities in p15, p16 and p53 tumor suppressor genes are commonly found in patients with MF.

**Prognosis and predictive factors**

The prognosis of patients with MF is dependent on stage, and in particular the type and extent of skin lesions and the presence of extracutaneous disease. Patients with limited patch/plaque stage MF have a similar life expectancy to an age-, sex-, and race-matched control population. In recent studies, 10-year disease-specific survivals were 97-98% for patients with limited patch/plaque disease (covering less than 10% of the skin surface), 83% for patients with generalized patch/plaque disease (covering more than 10% of the skin surface), 42% for patients with tumor stage disease, and about 20% for patients with histologically documented lymph node involvement. Patients with effaced lymph nodes, visceral involvement, and transformation into a large T-cell lymphoma have an aggressive clinical course. Patients usually die of systemic involvement or infections.

**Therapy**

As long as the disease is confined to the skin, skin-targeted therapies as photo(chemo)therapy (eg, PUVA), topical application of nitrogen mustard or chlorambucil (BCNU), or radiotherapy, including
total skin electron beam irradiation, are preferred.\textsuperscript{58-60} In patients with limited patch stage disease topical steroids or bexarotene gel can be used. Biologicals such as interferon alpha and other cytokines (eg, IL-12), traditional and new retinoids such as Bexarotene, and receptor-targeted cytotoxic fusion proteins (eg. DAB\textsubscript{389}IL-2; denileukin diftitix), are increasingly used in the treatment of MF.\textsuperscript{58, 60-63} However, the exact place of these new treatments, either as single agent therapy or in combination with other therapies (eg, PUVA) in the treatment of MF remains to be established. Multiagent chemotherapy is generally used in case of unequivocal lymph node or systemic involvement, or in cases with widespread tumor stage MF refractory to skin-targeted therapies, but should not be considered in early patch/plaque stage disease.\textsuperscript{64}

VARIANTS AND SUBTYPES OF MYCOSIS FUNGOIDES

Apart from the classical Alibert-Bazin type of MF, many clinical and/or histologic variants have been reported. Clinical variants, such as bullous and hyper- or hypopigmented MF have a clinical behaviour similar to that of classical MF, and are therefore not considered separately. In contrast, folliculotropic MF (MF-associated follicular mucinosis), pagetoid reticulosis and granulomatous slack skin have distinctive clinicopathologic features, and are therefore considered separately.

FOLLICULOTROPIC MF

\textbf{Definition}

Folliculotropic MF is a variant of MF characterized by the presence of folliculotropic infiltrates often with sparing of the epidermis, and preferential involvement of the head and neck area. Most cases show mucinous degeneration of the hair follicles (follicular mucinosis) and are traditionally designated as MF-associated follicular mucinosis. Similar cases, but without follicular mucinosis have been reported as folliculocentric or pilotropic MF.\textsuperscript{65} Recent studies showed no differences in clinical presentation and clinical behavior between cases of folliculotropic MF with or without associated follicular mucinosis, and suggested that cases with a preferential infiltration of hair follicles with or without the presence of mucin should be termed \textit{follicular MF} or \textit{folliculotropic MF}.\textsuperscript{66-68} In the WHO-EORTC classification, folliculotropic MF is preferred as the most appropriate term. From a biologic point of view, the most relevant feature in both cases with and without associated follicular mucinosis is the deep, follicular and perifollicular localization of the neoplastic infiltrates, which makes them less accessible to skin-targeted therapies.

\textbf{Clinical features}

Folliculotropic MF occurs mostly in adults, but may occasionally affect children and adolescents. Males are more often affected than females. Patients may present with grouped follicular papules,
acneiform lesions, indurated plaques and sometimes tumors, which preferentially involve and are most pronounced in the head and neck area. The skin lesions are often associated with alopecia, and sometimes with mucinorrhoea. Infiltrated plaques in the eyebrows with concurrent alopecia are a common and highly characteristic finding (Fig. 2A). Unlike in classical MF, pruritus is often severe, and may represent a good parameter of disease progression. Secondary bacterial infections are frequently observed.

**Histopathology**

Characteristic findings include the primarily perivascular and periadnexal localization of the dermal infiltrates with variable infiltration of the follicular epithelium by small, medium-sized or sometimes large hyperchromatic cells with cerebriform nuclei, and sparing of the epidermis (folliculotropism instead of epidermotropism) (Fig. 2B). Most cases show mucinous degeneration of the follicular epithelium (follicular mucinosis), as assessed with Alcian blue staining. There is often a considerable admixture of eosinophils and sometimes plasma cells. In most cases the neoplastic T-cells have a CD3+, CD4+, CD8- phenotype as in classical MF. An admixture of CD30-positive blast cells is common.

In some cases prominent infiltration of both follicular epithelium and eccrine sweat glands may be observed. Similar cases with prominent infiltration of eccrine sweat glands, often associated with alopecia, have been designated as syringotropic MF.

**Prognosis**

Recent studies described a disease-specific 5-year-survival of approximately 70-80% in patients with folliculotropic MF (see Table 2), which is similar to that of classical tumor stage MF, but significantly worse than that of patients with classical plaque stage MF.

**Treatment**

Because of the perifollicular localization of the dermal infiltrates, folliculotropic FM is often less responsive to skin-targeted therapies, such as PUVA and topical nitrogen mustard than classical plaque stage MF. In such cases total skin electron beam irradiation is an effective treatment, but sustained complete remissions are rarely achieved. Alternatively, PUVA combined with retinoids or interferon alpha may be considered, whereas persistent tumors can be effectively treated with local radiotherapy.
PAGETOID RETICULOSIS

Definition
Pagetoid reticulosis is a variant of MF characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic T-cells. The term pagetoid reticulosis should only be used for the localized type (Woringer-Kolopp type) and not for the disseminated type (Ketron-Goodman type). Generalized cases would currently likely be classified as aggressive epidermotropic CD8-positive CTCL, cutaneous gamma/delta-positive T-cell lymphoma or tumor stage MF.2, 25, 72

Clinical features
Patients present with a solitary psoriasiform or hyperkeratotic patch or plaque, which is usually localized on the extremities, and is slowly progressive. In contrast to classical MF, extracutaneous dissemination or disease-related deaths have never been reported.

Histopathology
The typical histologic picture shows a hyperplastic epidermis with marked infiltration by atypical pagetoid cells, singly or arranged in nests. The atypical cells have medium-sized or large, sometimes hyperchromatic and cerebriform nuclei, and abundant, vacuolated cytoplasm. The upper dermis may show a mixed infiltrate of lymphocytes or histiocytes, but does not contain neoplastic T cells.

Immunophenotype
The neoplastic T cells may have either a CD3+, CD4+, CD8- or a CD3+, CD4-, CD8+ phenotype. CD30 is often expressed.73,74

Treatment
The preferred mode of treatment is radiotherapy or surgical excision. In some instances topical nitrogen mustard or topical steroids may be an acceptable alternative.

GRANULOMATOUS SLACK SKIN

Definition
Granulomatous slack skin (GSS) is an extremely rare subtype of CTCL characterized by the slow development of folds of lax skin in the major skin folds and histologically by a granulomatous infiltrate with clonal T cells.75
**Clinical features**

This condition shows circumscribed areas of pendulous lax skin with a predilection for the axillae and groins. In approximately one third of the reported patients an association with Hodgkin’s lymphoma was observed, and association with classical MF has also been reported. Most patients have an indolent clinical course (see Table 2).

**Histopathology**

Fully developed lesions show dense granulomatous dermal infiltrates containing atypical T-cells with slightly indented to cerebriform nuclei, macrophages and often many multinucleated giant cells, and destruction of elastic tissue. The epidermis may show focal infiltration by small atypical T cells. The atypical T cells have a CD3+, CD4+, CD8- phenotype.

**Therapy**

Radiotherapy may be effective, but experience is limited. Rapid recurrences after surgical excision have been reported.

**SEZARY SYNDROME**

**Definition**

Sézary syndrome (SS) is defined historically by the triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in skin, lymph nodes and peripheral blood. In a recent report of the International Society for Cutaneous Lymphomas (ISCL) criteria recommended for the diagnosis of SS include one or more of the following: an absolute Sézary cell count of least 1000 cells per mm³, demonstration of immunophenotypical abnormalities (an expanded CD4+ T-cell population resulting in a CD4/CD8 ratio more than 10, loss of any or all of the T-cell antigens CD2, CD3, CD4 and CD5, or both); the demonstration of a T-cell clone in the peripheral blood by molecular or cytogenetic methods. It is acknowledged that SS is part of a broader spectrum of erythrodermic CTCL, and that alternative staging systems for assessment of the degree of peripheral blood involvement in these erythrodermic CTCL have been proposed. However, until the results of an ISCL study investigating the clinical validity of these proposals are available, demonstration of a T-cell clone (preferably of the same T-cell clone in skin and peripheral blood) in combination with one of the abovementioned cytomorphological or immunophenotypical criteria are suggested as minimal criteria for the diagnosis of SS to exclude patients with benign inflammatory condition simulating SS.

**Clinical features**
SS is a rare disease and occurs exclusively in adults. It is characterized by erythroderma, which may be associated with marked exfoliation, edema and lichenification, and which is intensely pruritic. Lymphadenopathy, alopecia, onychodystrophy, and palmoplantar hyperkeratosis are common findings.78

**Histopathology**

The histological features in SS may be similar to those in MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may sometimes be absent. In up to one third of biopsies from patients with otherwise classical SS the histologic picture may be non-specific.81,82 Involved lymph nodes characteristically show a dense, monotonous infiltrate of Sézary cells with effacement of the normal lymph node architecture.83 Bone marrow may be involved, but the infiltrates are often sparse and mainly interstitial.84

**Immunophenotype**

The neoplastic T-cells have a CD3+, CD4+, CD8- phenotype. In cases with a predominant CD3+, CD4-, CD8+ T-cell population in the skin and peripheral blood the diagnosis of actinic reticuloid should be considered.85 Circulating Sézary cells often show loss of CD7 and CD26.79

**Genetic features**

T-cell receptor genes are clonally rearranged. Demonstration of clonal T cells in the peripheral blood is considered as an important diagnostic criterion allowing differentiation between SS and benign forms of erythroderma.2,79,80 Recurrent chromosomal translocations have not been detected in SS, but complex karyotypes are common.86,87 Several studies have identified a consistent pattern of identical chromosomal abnormalities in SS, which was almost identical to that in MF, suggesting that both conditions represent parts of the same spectrum of disease with a similar pathogenesis.88,89 Chromosomal amplification of JUNB, a member of the AP-1 transcription factor complex involved in cell proliferation and Th2 cytokine expression by T cells, has been identified in SS.90,91

**Prognosis and predictive factors**

The prognosis is generally poor, with a median survival between 2 and 4 years, depending on the exact definition used.2,80 The disease-specific 5-year-survival of 52 SS patients included in the Dutch and Austrian registries was 24% (see Table 2). Most patients die of opportunistic infections that are due to immunosuppression.

**Therapy**
Extracorporeal photopheresis (ECP), either alone or in combination with other treatment modalities (e.g. Interferon alpha), has been reported as an effective treatment in SS and erythrodermic MF, with overall response rates of 30-80%, and complete response rates of 14-25%. This great variation in response rates may reflect differences in patient selection and/or concurrent therapies. The suggested superiority of ECP over the traditional low-dose chemotherapy regimens has not yet been substantiated by controlled randomized trials. Beneficial results have also reported of interferon alpha, either alone or in combination with PUVA therapy, prolonged treatment with a combination of low-dose chlorambucil (2-4 mg/day) and prednisone (10-20 mg/day) or with methotrexate (5-25 mg/week), but complete responses are uncommon. Skin-directed therapies like PUVA or potent topical steroids may be used as adjuvant therapy. Recent studies report beneficial effects of bexarotene and alemtuzumab (anti-CD52), but the long-term effects of these therapies remain to be established.

ADULT T-CELL LEUKEMIA/LYMPHOMA (ATLL)

Definition
ATLL is a T-cell neoplasm etiologically associated with the human T-cell leukemia virus 1 (HTLV-1). Skin lesions are generally a manifestation of widely disseminated disease. However, a slowly progressive form that may have only skin lesions has been described (smoldering variant).

Clinical features
ATLL is endemic in areas with a high prevalence of HTLV-1 in the population, such as southwest Japan, the Caribbean islands, South Americas, and parts of Central Africa. ATLL develops in 1% to 5% of seropositive individuals after more than two decades of viral persistence. Most patients present with acute ATLL characterized by the presence of leukemia, lymphadenopathy, organomegaly, hypercalcemia and in about 50% skin lesions, most commonly nodules or tumors (33%), generalized papules (22%) or plaques (19%). Chronic and smoldering variants frequently present with skin lesions, which may closely resemble MF, whereas circulating neoplastic T-cells are few or absent.

Histopathology
Skin lesions show a superficial or more diffuse infiltration of medium-sized to large T-cells with pleomorphic or polylobated nuclei, which often display marked epidermotropism. The histologic picture may be indistinguishable from MF. Skin lesions in the smoldering type may show sparse dermal infiltrates with only slightly atypical cells. The neoplastic T cells express a CD3+, CD4+, CD8- phenotype. CD25 is highly expressed.
Genetic features
T-cell receptor genes are clonally rearranged. Clonally integrated HTLV-1 genes are found in all cases, and are useful in differentiating between chronic or smoldering variants of ATLL and classical MF or SS.97

Prognosis and predictive factors
Clinical subtype is the main prognostic factor. Survival in acute and lymphomatous variants ranges from two weeks to more than one year. Chronic and smoldering forms have a more protracted clinical course and a longer survival, but transformation into an acute phase with an aggressive course may occur.95,96

Treatment
In most cases systemic chemotherapy is required.98,99 In chronic and smoldering cases mainly affecting the skin, skin-targeted therapies as in MF may be used.

PRIMARY CUTANEOUS CD30-POSITIVE LYMPHOPROLIFERATIVE DISORDERS

Primary cutaneous CD30-positive lymphoproliferative disorders (LPD) are the second most common group of CTCL, accounting for approximately 30% of CTCL (Table 2). This group includes primary cutaneous anaplastic large cell lymphoma (C-ALCL), lymphomatoid papulosis (LyP), and borderline cases. It is now generally accepted that C-ALCL and LyP form a spectrum of disease, and that histologic criteria alone are often insufficient to differentiate between these two ends of this spectrum.100 The clinical appearance and course are used as decisive criteria for the definite diagnosis and choice of treatment. The term “borderline case” refers to cases in which, despite careful clinicopathologic correlation, a definite distinction between C-ALCL and LyP cannot be made. Clinical examination during further follow-up will generally disclose whether the patient has C-ALCL or LyP.101

Primary cutaneous anaplastic large cell lymphoma

Definition
Primary cutaneous anaplastic large cell lymphoma (C-ALCL) is composed of large cells with an anaplastic, pleomorphic or immunoblastic cytomorphology and expression of the CD30 antigen by the majority (more than 75%) of tumor cells.13 There is no clinical evidence or history of LyP, MF or another type of CTCL.
Clinical features
C-ALCL affects mainly adults with a male to female ratio of 2-3:1. Most patients present with solitary or localized nodules or tumors, and sometimes papules, and often show ulceration.\(^\text{101,102}\) (Fig. 3). Multifocal lesions are seen in about 20% of the patients. The skin lesions may show partial or complete spontaneous regression, as in LyP. These lymphomas frequently relapse in the skin. Extracutaneous dissemination occurs in approximately 10% of the patients, and mainly involves the regional lymph nodes.

Histopathology
There is a diffuse, nonepidermotropic infiltrate with cohesive sheets of large CD30-positive tumor cells. In most cases the tumor cells have the characteristic morphology of anaplastic cells, showing round, oval or irregularly-shaped nuclei, prominent eosinophilic nucleoli and abundant cytoplasm (Fig. 3). Less commonly (20-25%), they have a non-anaplastic (pleomorphic or immunoblastic) appearance.\(^\text{101,103}\) Reactive lymphocytes are often present at the periphery of the lesions. Ulcerating lesions may show a LyP-like histology with an abundant inflammatory infiltrate of reactive T-cells, histiocytes, eosinophils and/or neutrophils, and relatively few CD30-positive cells. In such cases epidermal hyperplasia may be prominent.

Immunophenotype
The neoplastic cells generally show an activated CD4+ T-cell phenotype with variable loss of CD2, CD5 and/or CD3 and frequent expression of cytotoxic proteins (granzyme B, TIA-1, perforin).\(^\text{104,105}\) Some cases (<5%) have a CD8+ T-cell phenotype. CD30 must be expressed by the majority (more than 75%) of the neoplastic T-cells.\(^\text{106}\) Unlike systemic CD30-positive lymphomas, most C-ALCL express the cutaneous lymphocyte antigen (CLA), but do not express EMA and ALK (anaplastic lymphoma kinase), indicative of the 2;5 chromosomal translocation or its variants.\(^\text{2,107-108}\) Unlike Hodgkin and Reed-Sternberg cells in Hodgkin's disease, staining for CD15 is generally negative. Co-expression of CD56 is observed in rare cases, but does not appear to be associated with an unfavorable prognosis.\(^\text{109}\)

Genetic features
Most cases show clonal rearrangement of T-cell receptor genes. The (2;5)(p23;q35) translocation and its variants, which is a characteristic feature of systemic ALCL, is not or rarely found in C-ALCL.\(^\text{108}\)

Prognosis and predictive factors
The prognosis is usually favorable with a 10-year disease-related survival exceeding 90%.\(^\text{101,102}\) Patients presenting with multifocal skin lesions and patients with involvement of only regional lymph nodes have a similar prognosis to patients with only skin lesions.\(^\text{101}\) No difference in clinical presentation, clinical behavior or prognosis is found between cases with an anaplastic morphology and cases with a non-anaplastic (pleomorphic or immunoblastic) morphology.\(^\text{101,103}\)
**Treatment**
Radiotherapy or surgical excision is the first choice of treatment in patients presenting with a solitary or few localized nodules or tumors. Patients presenting with multifocal skin lesions can best be treated with radiotherapy in case of only a few lesions, or with low dose methotrexate as in LyP. Patients presenting with or developing extracutaneous disease or rare patients with rapidly progressive skin disease should be treated with doxorubicin-based multi-agent chemotherapy.

**Lymphomatoid papulosis**

**Definition**
Lymphomatoid papulosis (LyP) is defined as a chronic, recurrent, self-healing papulonecrotic or papulonodular skin disease with histologic features suggestive of a (CD30-positive) malignant lymphoma.

**Clinical features**
LyP generally occurs in adults (median age: 45 years; male to female ratio: 1.5-1), but may occur in children as well. LyP is characterized by the presence of papular, papulonecrotic and/or nodular skin lesions at different stages of development, predominantly on the trunk and limbs. Individual skin lesions disappear within 3 to 12 weeks, and may leave behind superficial scars (Fig. 3). The duration of the disease may vary from several months to more than 40 years. In up to 20% of patients LyP may be preceded by, associated with or followed by another type of malignant (cutaneous) lymphoma, generally MF, a (C-)ALCL or Hodgkin's lymphoma.

**Histopathology**
The histologic picture of LyP is extremely variable, and in part correlates with the age of the biopsied skin lesion. Three histologic subtypes of LyP (types A, B and C) have been described, which represent a spectrum with overlapping features. In LyP type A lesions, scattered or small clusters of large, sometimes multinucleated or Reed-Sternberg-like, CD30-positive cells are intermingled with numerous inflammatory cells, such as histiocytes, small lymphocytes, neutrophils and/or eosinophils. LyP, type C lesions demonstrate a monotonous population or large clusters of large CD30-positive T-cells with relatively few admixed inflammatory cells. LyP, type B is uncommon (<10%) and is characterized by an epidermotropic infiltrate of small atypical cells with cerebriform nuclei similar to that observed in MF.

**Immunophenotype**
The large atypical cells in the LyP type A and type C lesions have the same phenotype as the tumor cells in C-ALCL. The atypical cells with cerebriform nuclei in the LyP type B lesions have a CD3+, CD4+, CD8- phenotype and do not express CD30 antigen.

**Genetic features**
Clonally rearranged T-cell receptor genes have been detected in approximately 60-70% of LyP lesions. Identical rearrangements have been demonstrated in LyP lesions and associated lymphomas. The (2;5)(p23;q35) translocation is not detected in LyP.

**Prognosis and predictive factors**
LyP has an excellent prognosis. In a recent study of 118 LyP patients only five patients (4%) developed a systemic lymphoma, and only 2 patients (2%) died of systemic disease over a median follow-up period of 77 months. Risk factors for the development of a systemic lymphoma are unknown.

**Treatment**
Since a curative therapy is not available and none of the available treatment modalities affects the natural course of the disease, the short-term benefits of active treatment should be balanced carefully against the potential side effects. Low dose oral methotrexate (5-20 mg/week) is the most effective therapy to suppress the development of new skin lesions. Beneficial effects have been reported of PUVA and topical chemotherapy. However, after discontinuation of treatment the disease generally relapses within weeks or months. Therefore, in patients with relatively few and non-scarring lesions long-term follow-up without active treatment should be considered.

**SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA**

**Definition**
Subcutaneous panniculitis-like T-cell lymphoma (SPTL) is defined as a cytotoxic T-cell lymphoma characterized by the presence of primarily subcutaneous infiltrates of small, medium-sized or large pleomorphic T-cells and many macrophages, predominantly affecting the legs, and often complicated by a hemophagocytic syndrome. Recent studies suggest that at least two groups of SPTL with a different histology, phenotype and prognosis can be distinguished. Cases with an α/β+ T-cell phenotype are usually CD8-positive, are restricted to the subcutaneous tissue (no dermal and/or epidermal involvement), and often run an indolent clinical course. In contrast, SPLTL with a γ/δ T-cell phenotype, approximately 25% of all cases, are typically CD4-, CD8- and often co-express CD56, the neoplastic infiltrates are not confined to the subcutaneous tissue, but may involve the epidermis and/or dermis as well, and invariably have a very poor prognosis. In the WHO-EORTC classification the term
SPTL is only used for cases with an $\alpha/\beta^+$ T-cell phenotype, whereas cases with a $\gamma/\delta^+$ T-cell phenotype are included in the category of cutaneous $\gamma/\delta$ T-cell lymphomas.\(^{32}\)

**Clinical features**

SPTCL occur in adults as well as in young children, and both sexes are equally affected. Patients generally present with solitary or multiple nodules and plaques, which mainly involve the legs, or may be more generalized (Fig. 4A). Ulceration is uncommon. Systemic symptoms such as fever, fatigue and weight loss may be present. The disease may be complicated by a hemophagocytic syndrome, which is generally associated with a rapidly progressive course.\(^{117}\) However, a hemophagocytic syndrome is probably less common than in cutaneous $\gamma/\delta$ T-cell lymphomas with panniculitis-like lesions. Dissemination to extracutaneous sites is rare. SPTL may be preceded for years or decades by an seemingly benign panniculitis.\(^{15,17,117}\)

**Histopathology**

Histopathology reveals subcutaneous infiltrates simulating a panniculitis showing small, medium-sized or sometimes large pleomorphic T cells with hyperchromatic nuclei and often many macrophages. The overlying epidermis and dermis are typically uninvolved.\(^{16,116}\) Rimming of individual fat cells by neoplastic T cells is a helpful, though not completely specific diagnostic feature.\(^{32}\) (Fig. 4B). Necrosis, karyorrhexis and cytophagocytosis are common findings. In the early stages the neoplastic infiltrates may lack significant atypia and a heavy inflammatory infiltrate may predominate.\(^{15,17,117}\)

**Immunophenotype**

These lymphomas show a $\alpha/\beta^+$, CD3+, CD4-, CD8+ T-cell phenotype, with expression of cytotoxic proteins.\(^{14,16,17,32}\) (Fig. 4C). CD30 and CD56 are rarely, if ever, expressed.

**Genetic features**

The neoplastic T cells show clonal TCR gene rearrangements. Specific genetic abnormalities have not been identified. EBV is absent.

**Prognosis and predictive factors**

In contrast to prior reports indicating that patients with a SPTL have a rapidly fatal course, recent studies suggest that many patients with a SPTL (with a CD8+, $\alpha/\beta^+$ T-cell phenotype) have a protracted clinical course with recurrent subcutaneous lesions but without extracutaneous dissemination or the development of a hemophagocytic syndrome.\(^{17,32}\) Based on the few published reports in which appropriate phenotyping was performed, the 5-year-survival of such patients may be over 80%\(^{32}\), which is consistent with the data presented in Table 2.
Treatment
Patients have generally been treated with doxorubicin-based chemotherapy and radiotherapy.12-17 However, recent studies suggest that many patients can be controlled for long periods of time with systemic corticosteroids.17, 32

EXTRANODAL NK/T-CELL LYMPHOMA, NASAL TYPE

Definition
Extranodal NK/T-cell lymphoma, nasal type is a nearly always EBV positive lymphoma of small, medium or large cells usually with an NK-cell, or more rarely a cytotoxic T-cell phenotype. The skin is the second most common site of involvement after the nasal cavity/nasopharynx, and skin involvement may be a primary or secondary manifestation of the disease. Since both groups show an aggressive clinical behavior and require the same type of treatment, distinction between “primary” and “secondary” cutaneous involvement seems not useful for this category.16,19,32,118,119 Therefore, the WHO classification-derived term extranodal NK/T-cell lymphoma, nasal type rather than (primary) cutaneous NK/T-cell lymphoma, nasal type was preferred.

Clinical features
Patients are adults with a predominance of males. This lymphoma is more common in Asia, Central America and South America. Patients generally present with multiple plaques or tumors preferentially on the trunk and extremities, or in case of nasal NK/T-cell lymphoma with a midfacial destructive tumor, previously also designated lethal midline granuloma.18,19,32,119-122 Ulceration is common (Fig. 5A). Systemic symptoms such as fever, malaise and weight loss may be present, and some cases are accompanied by a haemophagocytic syndrome. The disease is closely related to aggressive NK-cell leukaemia, which also may have cutaneous manifestations, and is also EBV-associated.

Histopathology
These lymphomas show dense infiltrates involving the dermis and often the subcutis. Epidermotropism may be present. Prominent angiocentricity and angiodestruction are often accompanied by extensive necrosis.18,19 NK/T-cell lymphoma has a broad cytological spectrum ranging from small to large cells, with most cases consisting of medium sized cells. The cells may have irregular or oval nuclei, moderately dense chromatin, and pale cytoplasm. In some cases a heavy inflammatory infiltrate of small lymphocytes, histiocytes, plasma cells and eosinophils can be seen.
**Immunophenotype**

The neoplastic cells express CD2, CD56, cytoplasmic CD3ɛ and cytotoxic proteins (TIA-1, granzyme B, perforin), but lack surface CD3. In rare CD56 negative cases detection of EBV by in-situ-hybridization and expression of cytotoxic proteins are required for diagnosis. (Fig. 5B). LMP-1 is inconsistently expressed.

**Genetic features**

The T-cell receptor is usually in germ line configuration, but can be rearranged in rare tumors with a cytotoxic T-cell phenotype. EBV is expressed almost in all cases, suggesting a pathogenetic role of this virus.

**Prognosis and predictive factors**

Nasal type NK/T-cell lymphoma presenting in the skin is a highly aggressive tumour with a median survival of less than 12 months. The most important factor predicting poor outcome is the presence of extracutaneous involvement at presentation. In patients presenting with only skin lesions a median survival of 27 months was reported, compared to 5 months for patients presenting with cutaneous and extracutaneous disease. CD30+, CD56+ cases reported to have a better prognosis may have been examples of C-ALCL with co-expression of CD56.

**Therapy**

Systemic chemotherapy is the first choice of treatment, but the results are disappointing.

**Variant**

Hydroa vacciniforme-like CTCL is a rare type of EBV-associated lymphoma of CD8+ cytotoxic T cells, which affects children almost exclusively in Latin America and Asia. Patients present with a papulovesicular eruption clinically resembling hydroa vacciniforme, particularly on the face and upper extremities (sunexposed areas). The prognosis is poor.

**PRIMARY CUTANEOUS PERIPHERAL T-CELL LYMPHOMA, UNSPECIFIED**

PTL, unspecified in the WHO classification represent a heterogeneous group which includes all T-cell neoplasms that do not fit into any of the better defined subtypes of T-cell lymphoma/leukemia. Recent studies have suggested that primary cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma, cutaneous gamma-delta T-cell lymphoma, and primary cutaneous small-medium CD4+ T-cell lymphoma can be separated out as provisional entities. For the remaining diseases that do not fit
into either of these provisional entities the designation PTL, unspecified, is maintained. In all cases a diagnosis of MF must be ruled out by complete clinical examination and an accurate clinical history.

Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma (provisional entity)

Definition
CTCL characterized by a proliferation of epidermotropic CD8-positive cytotoxic T-cells and an aggressive clinical behavior. Differentiation from other types of CTCL expressing a CD8-positive cytotoxic T-cell phenotype, as observed in more than 50% of patients with pagetoid reticulosis, and rare cases of MF, LyP, and C-ALCL, is based on the clinical presentation and clinical behavior. In these latter conditions no difference in clinical presentation or prognosis between CD4+ and CD8+ cases is found.

Clinical features
Clinically, these lymphomas are characterized by the presence of localized or disseminated eruptive papules, nodules and tumors showing central ulceration and necrosis or by superficial, hyperkeratotic patches and plaques. The clinical features are very similar to those observed in patients with a cutaneous γ/δ T-cell lymphoma and cases described as generalized pagetoid reticulosis (Ketron-Goodman type) in the past. These lymphomas may disseminate to other visceral sites (lung, testis, central nervous system, oral mucosa), but lymph nodes are often spared.

Histopathology
Histologically these lymphomas show an acanthotic or atrophic epidermis, necrotic keratinocytes, ulceration and variable spongiosis, sometimes with blister formation. Epidermotropism is often pronounced ranging from a linear distribution to a pagetoid pattern throughout the epidermis (Fig. 6B). Invasion and destruction of adnexal skin structures are commonly seen. Angiocentricity and angioinvasion may be present. Tumour cells are small-medium or medium-large with pleomorphic or blastic nuclei.

Immunophenotype
The tumor cell have a betaF1+, CD3+, CD8+, granzyme B+, perforin+, TIA-1+, CD45RA+, CD45RO-, CD2-, CD4-, CD5-, CD7-/+ phenotype. EBV is generally negative.
**Genetic features**

The neoplastic T-cells show clonal TCR gene rearrangements. Specific genetic abnormalities have not been described.

**Prognosis and predictive factors**

These lymphomas often have an aggressive clinical course with a median survival of 32 months.\(^{25}\) There is no difference in survival between cases with a small or large cell morphology.\(^{11}\)

**Therapy**

Patients are generally treated with doxorubicin-based multi-agent chemotherapy.

**Cutaneous gamma/delta T-cell lymphoma (provisional entity)**

**Definition**

Cutaneous gamma/delta T-cell lymphoma (CGD-TCL) is a lymphoma composed of a clonal proliferation of mature, activated gamma/delta T cells with a cytotoxic phenotype. This group includes cases previously known as SPTCL with a gamma/delta phenotype. A similar and possibly related condition may present primarily in mucosal sites.\(^{28}\) Whether cutaneous and mucosal gamma/delta TCL are all part of a single disease, i.e. *muco-cutaneous gamma/delta TCL*, is not yet clear.\(^{29,122}\) Distinction between ‘primary’ and ‘secondary’ cutaneous cases is not useful in this group, since both groups have a very grim prognosis.

**Clinical features**

CGD-TCL generally present with disseminated plaques and/or ulceronecrotic nodules or tumors, particularly on the extremities, but other sites may be affected as well.\(^{27-31}\) Involvement of mucosal and other extranodal sites is frequently observed, but involvement of lymph nodes, spleen or bone marrow is uncommon. A haemophagocytic syndrome may occur in patients with panniculitis-like tumors.\(^{12,31}\)

**Histopathology**

Three major histologic patterns of involvement can be present in the skin: epidermotropic, dermal and subcutaneous. Often more than one histologic pattern is present in the same patient in different biopsy specimens or within a single biopsy specimen.\(^{27,31}\) The neoplastic cells are generally medium to large in size with coarsely clumped chromatin. Large blastic cells with vesicular nuclei and prominent nucleoli are infrequent. Apoptosis and necrosis are common, often with angioinvasion. The subcutaneous cases may show rimming of fat cells, similar to SPTCL of alpha/beta origin.
**Immunophenotype**
The tumor cells characteristically have a betaF1-, CD3+, CD2+, CD5-, CD7+/-, CD56+ phenotype with strong expression of cytotoxic proteins. Most cases lack both CD4 and CD8, though CD8 may be expressed in some cases. In frozen sections the cells are strongly positive for TCR-delta. If only paraffin sections are available, the absence of betaF1 may be used to infer a gamma/delta origin under appropriate circumstances.

**Genetic features**
The cells show clonal rearrangement of the TCR gamma gene. TCR beta may be rearranged or deleted, but is not expressed. EBV is generally negative.

**Prognosis and predictive factors**
Most patients have aggressive disease resistant to multiagent chemotherapy and/or radiation. In a recent series of 33 patients a median survival of 15 months was noted. This study showed a trend for decreased survival for patients who had subcutaneous fat involvement in comparison with patients who had epidermal or dermal disease only.

**Therapy**
Patients should be treated with systemic chemotherapy, but the results are often disappointing.

**Primary cutaneous CD4-positive small/medium-sized pleomorphic T-cell lymphoma (provisional entity)**

**Definition:**
CTCL defined by a predominance of small to medium-sized CD4-positive pleomorphic T-cells without (a history of) patches and plaques typical of MF and in most cases a favorable clinical course. In contrast to the EORTC classification, in the WHO-EORTC classification the term small/medium-sized pleomorphic CTCL is restricted to cases with a CD4+ T-cell phenotype. Cases with a CD3+, CD4-, CD8+ phenotype usually have a more aggressive clinical course are included in the group of aggressive epidermotropic CD8-positive CTCL.

**Clinical features**
Characteristically, these lymphomas present with a solitary plaque or tumor, generally on the face, the neck or the upper trunk (Fig. 7A). Less commonly, they present with one or several papules, nodules or tumors.
**Histological features**
These lymphomas show dense, diffuse or nodular infiltrates within the dermis with tendency to infiltrate the subcutis. Epidermotropism may be present focally. There is a predominance of small/medium-sized pleomorphic T cells (Fig. 7B). A small proportion (<30%) of large pleomorphic cells may be present. In some cases a considerable admixture with small reactive lymphocytes and histiocytes may be observed.

**Immunophenotype**
By definition these lymphomas have a CD3+, CD4+, CD8-, CD30- phenotype sometimes with loss of pan T cell markers. Cytotoxic proteins are generally not expressed.

**Genetic features**
The TCR genes are clonally rearranged. No consistent cytogenetic abnormalities have yet been identified. Demonstration of an aberrant T-cell phenotype and clonality are useful criteria to differentiate these small/medium-sized pleomorphic CTCL from pseudo-T-cell lymphomas, which may also present with a solitary plaque or nodule.

**Prognosis and predictive factors**
These lymphomas have a rather favorable prognosis with an estimated 5-year survival of approximately 60-80% (see Table 2). Particularly, cases presenting with a solitary or localized skin lesions seem to have an excellent prognosis.

**Therapy**
In patients with solitary localized skin lesions surgical excision or radiotherapy is the preferred mode of treatment. Cyclophosphamide as single-agent therapy and interferon alpha have been reported effective in patients with more generalized skin disease. However, the optimal treatment for this group has still to be defined.

**Primary cutaneous peripheral T-cell lymphoma, unspecified**

**Definition**
The designation PTL, unspecified is maintained for cutaneous T-cell lymphomas that do not fit into any of the better defined subtypes of CTCL. Hence, other categories of T-cell lymphoma must be excluded. These include the three provisional entities described above.
**Clinical features**

Patients are commonly adults, who present with solitary or localized, but more frequently generalized nodules or tumors.\textsuperscript{2,4,10,11} No sites of predilection have been recorded.

**Histopathology**

Skin lesions show nodular or diffuse infiltrates with variable numbers of medium-sized to large pleomorphic or immunoblast-like T cells. Epidermotropism is generally mild or absent. Large neoplastic cells represent at least 30\% of the total tumor cell population.\textsuperscript{10}

**Immunophenotype**

Most cases show an aberrant CD4+ T-cell phenotype with variable loss of pan-T cell antigens. CD30 staining is negative or restricted to few scattered tumor cells. Rare cases may show co-expression of CD56. Expression of cytotoxic proteins is uncommon.\textsuperscript{11}

**Prognosis and predictive factors**

The prognosis is generally poor with 5-year survival rates of less than 20\%.\textsuperscript{2,4,5,10,11} (see Table 2). No statistical differences in survival were found between cases presenting with solitary/localized lesions and cases presenting with generalized skin lesions.\textsuperscript{11}

**Treatment**

Patients should be treated with multi-agent chemotherapy.

---

**CD4+/CD56+ HEMATOGERMIC NEOPLASM (BLASTIC NK-CELL LYMPHOMA)**

**Definition**

In the WHO classification blastic NK-cell lymphoma was included as a clinically aggressive neoplasm with a high incidence of cutaneous involvement and risk of leukaemic dissemination. The blastic cytological appearance and CD56 expression initially suggested an NK-precursor origin.\textsuperscript{3} More recent studies suggest derivation from a plasmacytoid dendritic cell precursor.\textsuperscript{23,24} CD4+/CD56+ hematodermic neoplasm\textsuperscript{22} and early plasmacytoid dendritic cell leukemia/lymphoma\textsuperscript{21} have been suggested as more appropriate terms for this condition.

**Clinical features**

CD4+/CD56+ hematodermic neoplasm commonly presents in the skin with solitary or multiple nodules or tumors with or without concurrent extracutaneous localizations.\textsuperscript{21-24,32} (Fig. 8A). About half
of the patients have nodal or bone marrow involvement at presentation. Most patients presenting with only skin lesions rapidly develop involvement of bone marrow, peripheral blood, lymph nodes and extranodal sites. CD4+/CD56+ hematodermic neoplasm should be differentiated above all from myelomonocytic leukemia cutis, and are conceptually similar to so-called “aleukemic leukemia cutis”.

**Histopathology**

These lymphomas show non-epidermotropic, monotonous infiltrates of medium-sized cells with finely dispersed chromatin, and absent or indistinct nucleoli resembling lymphoblasts or myeloblasts. (Fig. 8B). The cells have sparse cytoplasm. Mitotic figures are frequent. Inflammatory cells are absent. There is generally no necrosis or angioinvasion.

**Immunophenotype**

The tumour cells usually have a CD4+, CD56+, CD8-, CD7 +/-, CD2-/+, CD45RA+ phenotype, but do not express surface and cytoplasmic CD3 or cytotoxic proteins. (Fig. 8C). TdT and CD68 may be positive. Since lymphoblastic and myeloblastic neoplasms can also be positive for CD56, stains for CD3 and myeloperoxidase should always be performed in order to exclude these entities. The cells express CD123 and TCL1, both of which support a relationship to plasmacytoid dendritic cells.

**Genetic features**

T-cell receptor genes are in germline configuration. Tumour cells are negative for EBV.

**Prognosis and predictive factors**

CD4+/CD56+ hematodermic neoplasm is an aggressive disease with a poor prognosis (median survival, 14 months). Systemic chemotherapy usually results in a complete remission, but quick relapses unresponsive to further chemotherapy are the rule. No significant difference in survival is found between patients presenting with skin lesions with or without concurrent extracutaneous disease.

**Therapy**

Recent studies suggest that patients can best be treated with regimens used in acute leukemias.

**CUTANEOUS B-CELL LYMPHOMAS**

**PRIMARY CUTANEOUS MARGINAL ZONE B-CELL LYMPHOMA**
Definition
Primary cutaneous marginal zone B-cell lymphoma (PCMZL) is an indolent lymphoma composed of small B cells including marginal zone (centrocyte-like) cells, lymphoplasmacytoid cells and plasma cells. It includes cases previously designated as primary cutaneous immunocytoma and cases of cutaneous follicular lymphoid hyperplasia with monotypic plasma cells. Exceptional cases of primary cutaneous plasmacytoma without underlying multiple myeloma (extramedullary plasmacytoma of the skin) show considerable overlap with PCMZL and are therefore included in this category. PCMZL is considered part of the broad group of extranodal marginal zone B-cell lymphomas commonly involving mucosal sites, so called MALT (mucosa associated lymphoid tissue) lymphomas.

Clinical features
In most cases PCMZL presents with red to violaceous papules, plaques or nodules localized preferentially on the trunk or extremities, especially the arms. In contrast to PCFCL, presentation with multifocal skin lesions is frequent (Fig. 9). Ulceration is uncommon. PCMZL have a tendency to recur in the skin, but dissemination to extracutaneous sites is exceedingly rare. In some cases spontaneous resolution of the skin lesions may be observed. The development of anetoderma in spontaneously resolving lesions has been observed. An association with B. burgdorferi infection has been reported in a significant minority of European cases of PCMZL, but not in Asian cases or cases from the United States. Associated auto-immune diseases are uncommon in PCMZL, but rather suggest secondary cutaneous involvement of a systemic lymphoma.

Histopathology
These lymphomas show nodular to diffuse infiltrates with sparing of the epidermis. The infiltrates are composed of small lymphocytes, marginal zone B-cells (centrocyte-like cells), lymphoplasmacytoid cells and plasma cells, admixed with small numbers of centroblast- or immunoblast-like cells and many reactive T cells. Reactive germinal centers are frequently observed. They may be surrounded by a population of small to medium-sized cells with irregular nuclei, inconspicuous nucleoli and abundant pale cytoplasm (marginal zone B-cells). Monotypic plasma cells are often located at the periphery of the infiltrates and in the superficial dermis beneath the epidermis. PAS-positive intranuclear or intracytoplasmic inclusions may be present in cases with a predominance of lymphoplasmacytoid cells. PCMZLs rarely show transformation into a diffuse large B cell lymphoma, but a relative increase in large transformed cells can be seen in some cases.

Immunophenotype
The marginal zone B-cells express CD20, CD79a and bcl-2, but are negative for CD5, CD10, and bcl-6, which may be useful in distinction from PCFCL. Reactive germinal centers are typically bcl-
6+, CD10+ and bcl-2-. Plasma cells express CD138 and CD79a, but generally not CD20, and show monotypic cytoplasmic immunoglobulin light chain expression on paraffin sections.

**Genetic features**
Immunoglobulin heavy chains (IgH) are clonally rearranged. Recent studies suggest the presence of the t(14;18)(q32;q21) involving the IGH gene on chromosome 14 and the MLT gene on chromosome 18 in a proportion of PCMZL. However, other translocations observed in gastric MALT lymphomas, such as t(11;18)(q21;q21) and t(1;14)(p22;q32) have not been found in PCMZL.

**Prognosis and predictive factors**
The prognosis of PCMZL is excellent with a 5-year-survival close to 100% (see Table 2).

**Therapy**
Patients with a solitary or a few lesions can be treated with radiotherapy or surgical excision. In patients with associated *B. burgdorferi* infection systemic antibiotics should be tried first. For patients presenting with multifocal skin lesions chlorambucil or intralesional or subcutaneous administration of interferon alpha may produce complete responses in approximately 50% of patients. Very good results have also been obtained with the use of systemic or intralesional anti-CD20 antibody (Rituximab). In patients showing frequent skin relapses topical or intralesional steroids may be considered, or alternatively an expectant strategy can be followed, similar to that used in other indolent B-cell lymphomas and leukemias.

**PRIMARY CUTANEOUS FOLLICLE CENTER LYMPHOMA**

**Definition**
Primary cutaneous follicle center lymphoma (PCFCL) is defined as a tumor of neoplastic follicle center cells, usually a mixture of centrocytes (small and large cleaved follicle center cells) and variable numbers of centroblasts (large noncleaved follicle center cells with prominent nucleoli), with a follicular, a follicular and diffuse or a diffuse growth pattern, which generally present on the head or trunk. Lymphomas with a diffuse growth pattern and a monotonous proliferation of centroblasts and immunoblasts are, irrespective of site, excluded and are classified as PCLBCL (see Table 3).

**Clinical features**
PCFCL has a characteristic clinical presentation with solitary or grouped plaques and tumors, preferentially located on the scalp or forehead or on the trunk, and rarely on the legs. (Fig. 10A). Particularly on the trunk these tumors may be surrounded by erythematous papules and slightly
indurated plaques, which may precede the development of tumorous lesions for months or even many years. In the past PCFCL with such a typical presentation on the back were referred to as “reticulohistiocytoma of the dorsum” or “Crosti’s lymphoma”.\textsuperscript{34,148} (Fig. 10B). Presentation with multifocal skin lesions is observed in a small minority of patients, but is not associated with a more unfavourable prognosis.\textsuperscript{42,149} If left untreated the skin lesions gradually increase in size over years, but dissemination to extracutaneous sites is uncommon.

**Histopathology**

PCFCL show nodular to diffuse infiltrates with almost constant sparing of the epidermis. The histologic picture is variable, which relates primarily to the age and the growth rate of the biopsied skin lesion as well as the location.\textsuperscript{35,39} A clear-cut follicular growth pattern is more commonly observed in lesions arising on the scalp than those presenting on the trunk.\textsuperscript{150} Small and early lesions contain a mixture of centrocytes, relatively few centroblasts and many reactive T cells. Large centrocytes, often multilobated, are a common feature of PCFCL (Fig. 10C). The large neoplastic B-cells may have a fibroblast-like appearance. In small and/or early lesions a clear-cut follicular growth pattern or more often remnants of a follicular growth pattern may be observed. If present, the abnormal follicles are composed of malignant bcl-6+ follicle center cells enmeshed in a network of CD21+ or CD35+ follicular dendritic cells. The follicles are ill-defined, lack tingible body macrophages and generally have a reduced or absent mantle zone.\textsuperscript{150,151} With progression to tumorous lesions the neoplastic B-cells increase both in number and size, whereas the number of reactive T-cells steadily decreases.\textsuperscript{35,39} Follicular structures, if present before, are no longer visible except for occasional scattered CD21+ or CD35+ follicular dendritic cells. Tumorous skin lesions generally show a monotonous population of large follicle center cells, generally large centrocytes and multilobated cells and in rare cases spindle-shaped cells, with a variable admixture of centroblasts and immunoblasts.\textsuperscript{34,35,39,42,152} Usually, a prominent stromal component is present.

**Immunophenotype**

The neoplastic cells express the B-cell-associated antigens CD20 and CD79a, and may show monotypic staining for surface immunoglobulins (sIg). However, absence of detectable sIg is common in tumorous lesions showing a diffuse population of large follicle center cells. PCFCL consistently express bcl-6.\textsuperscript{141,142,151} CD10 expression is particularly observed in cases with a follicular growth pattern, but is uncommon in PCFCL with a diffuse growth pattern.\textsuperscript{142,153} Staining for CD5 and CD43 is negative. Unlike nodal and secondary cutaneous follicular lymphomas, PCFCL do not express bcl-2 protein or show faint bcl-2 staining in a minority of neoplastic B-cells.\textsuperscript{36,41,150} (see comments). Staining for MUM-1/IRF4 is negative.\textsuperscript{40} (Fig. 10C).
**Genetic features**

Clonally rearranged immunoglobulin genes are present. Somatic hypermutation of variable heavy and light chain genes has been demonstrated, which further supports the follicle center cell origin of these lymphomas. In most studies PCFCL, including cases with a follicular growth pattern, do not show the t(14;18), which is characteristically found in systemic follicular lymphomas and a proportion of systemic diffuse large B-cell lymphomas. Inactivation of p15 and p16 tumor suppressor genes by promoter hypermethylation has been reported in about 10% and 30% of PCFCL, respectively. Chromosomal imbalances have been identified by comparative genomic hybridization (CGH) analysis in a minority of PCFCL, but a consistent pattern has not yet emerged. In a recent study using interphase fluorescence in situ hybridization no evidence for translocations involving IgH, myc or bcl-6 loci were found. PCFCL have the gene expression profile of germinal center-like large B-cell lymphomas.

**Prognosis and predictive factors**

Irrespective of the growth pattern (follicular or diffuse), the number of blast cells or the presence of either localized or multifocal skin disease these PCFCL have an excellent prognosis with a 5-year-survival over 95%. A recent study suggests that strong expression of bcl-2 in PCFCL with a diffuse large cell histology is associated with a more unfavourable prognosis.

**Therapy**

In patients with localized or few scattered skin lesions radiotherapy is the preferred mode of treatment, even in cases with a predominance of large “cleaved” cells. Cutaneous relapses, observed in approximately 20% of patients, do not indicate progressive disease and can be treated with radiotherapy as well. Anthracycline-based chemotherapy is required only in patients with very extensive cutaneous disease, patients with extremely thick skin tumors and patients developing extracutaneous disease. Recent studies report beneficial effects of systemic or intralesional administration of anti-CD20 antibody (Rituximab) therapy in small series of PCFCL, but the long-term effects of this approach have yet to be determined.

**Comment**

Characteristically, PCFCL do not express bcl-2 protein, - or show faint bcl-2 staining in a minority of tumor cells -, and do not show the t(14;18). However, recent studies report the presence of t(14;18) and/or bcl-2 expression in a significant minority of PCFCL. Whether these discrepant results are the result of differences in patient selection (e.g. incomplete staging) or different definitions for bcl-2 positivity or represent regional differences is as yet unknown. Importantly, in PCFCL with a follicular growth pattern there are no differences in clinical presentation and behaviour between bcl-2 and/or t(14;18) positive and negative cases. In contrast, recent studies suggest
that expression of bcl-2 protein by more than 50% of the neoplastic B-cells in PCFCL with a diffuse proliferation of large centrocytes, observed in ca. 15% of cases, is associated with a more unfavourable prognosis. Further studies are warranted to define the clinical and biological significance of bcl-2 expression and/or the presence of t(14;18) observed in some cases of PCFCL. Notwithstanding, demonstration of bcl-2 expression and/or t(14;18) should always raise suspicion of a systemic lymphoma involving the skin secondarily.

PRIMARY CUTANEOUS DIFFUSE LARGE B-CELL LYMPHOMA, LEG TYPE

Definition
PCLBCL with a predominance or confluent sheets of centroblasts and immunoblasts, characteristically presenting with skin lesions on the (lower) legs. Uncommonly, skin lesions with a similar morphology and phenotype can arise at sites other than the legs.

Clinical features
PCLBCL, leg type predominantly affects elderly patients, particularly females. Patients present with generally rapidly growing red or bluish-red tumors on one or both (lower) legs (Fig. 11A). In contrast to the group of PCFCL, these lymphomas more often disseminate to extracutaneous sites and have a more unfavorable prognosis. Reports on PCLBCL, leg type arising at sites other than the leg are few. In a recent European multicenter study 16 of 17 patients presented with solitary or localized skin lesions either on the trunk or head, and 7 of 17 patients developed extracutaneous disease.

Histopathology
These lymphomas show diffuse infiltrates, which often extend into the subcutaneous tissue. These infiltrates generally show a monotonous population or confluent sheets of centroblasts and immunoblasts. Mitotic figures are frequently observed. Small B cells are lacking and reactive T cells are relatively few and often confined to perivascular areas. A prominent stromal reaction as in PCFCL is not observed.

Immunophenotype
The neoplastic B cells express monotypic slg and/or clg and B-cell-associated antigens CD20 and CD79a. In contrast to the group of PCFCL, PCLBCL, leg type show strong bcl-2 expression, also in cases not located on the legs. Bcl-6 is expressed by most cases, whereas CD10 staining is generally absent. Unlike PCFCL, most PCLBCL, leg type express MUM-1/IRF4 protein.
Genetic features

The t(14;18) is not found in PCLBCL, although strong bcl-2 expression is common in this group. In some cases bcl-2 overexpression may result from chromosomal amplification of the bcl-2 gene. Inactivation of p15 and p16 tumor suppressor genes by promotor hypermethylation has been detected in 11% and 44% of PCLBCL, respectively. Chromosomal imbalances have been identified in up to 85% of PCLBCL, with gains in 1q and 7p and loss of 6q as most common findings. Recent studies demonstrated translocations involving myc, bcl-6 and IgH genes in 11 of 14 PCLBCL-leg, but not in patients with a PCFCL with a diffuse infiltration of large centrocytes. Recent studies suggest that PCLBCL-leg have an activated B-cell gene expression profile.

Prognosis and predictive features

The 5-year survival of 78 cases included in the Dutch and Austrian registries was 55% (Table 2). PCLBCL on the leg have an inferior prognosis compared to PCLBCL presenting at other sites. The presence of multiple skin lesions at diagnosis is a significant adverse risk factor. In a recent study, patients presenting with a single skin tumor on one leg had a disease-related 5-year-survival of 100%, whereas patients presenting with multiple skin lesions on one or both legs had a disease-related 5-year-survival of 45% and 36%, respectively.

Therapy

These lymphomas should be treated as systemic diffuse large B-cell lymphomas with anthracycline-based chemotherapy. In patients presenting with a single small skin tumor radiotherapy may sometimes be considered. Systemic administration of anti-CD20 antibody (Rituximab) has proved effective in some patients, but long-term follow-up data are not available and the place of rituximab in the treatment of PCLBCL, either as single agent therapy or in combination with systemic chemotherapy remains to be established.

PRIMARY CUTANEOUS DIFFUSE LARGE B-CELL LYMPHOMA, OTHER

The term PCLBCL, other refers to rare cases of large B-cell lymphomas arising in the skin, which do not belong to the group of PCLBCL, leg type or the group of PCFCL. These cases include morphological variants of diffuse large B-cell lymphoma, such as anaplastic or plasmablastic subtypes or T-cell/histiocyte rich large B-cell lymphomas. Such cases are generally a skin manifestation of a systemic lymphoma. Plasmablastic lymphomas are seen almost exclusively in the setting of HIV infection or other immune deficiencies. Some of these cases had only skin lesions at presentation. Rare cases of primary cutaneous T-cell/histiocyte-rich B-cell lymphoma, characterized by the presence of large scattered B cells in a background of numerous reactive T cells, have been reported.
Clinically, they show similarities with the groups of PCFCL and PCMZL. These lymphomas commonly present with skin lesions on the head, the trunk or the extremities, and may in fact represent an exaggerated T-cell infiltrate in association with other forms of CBCL. Unlike their nodal counterparts, they appear to have an excellent prognosis.\textsuperscript{173,174} In addition, rare cases of primary cutaneous intravascular large B-cell lymphoma may be included in this category PCLBCL, other.

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma is a well-defined subtype of large B-cell lymphoma, defined by an accumulation of large neoplastic B-cells within blood vessels. These lymphomas preferentially affect the central nervous system, lungs and skin and are generally associated with a poor prognosis.\textsuperscript{175} Patients often have widely disseminated disease, but cases with only skin involvement may occur. Clinically, intravascular large B-cell lymphoma may present with violaceous patches and plaques or teleangiectatic skin lesions usually on the (lower) legs or the trunk.\textsuperscript{175,176} Patients presenting with only skin lesions appear to have a significantly better survival than patients with other clinical presentations (3-year overall survival 56\% versus 22\%).\textsuperscript{176} Interestingly, colonization of cutaneous cherry haemangiomas by neoplastic cells as the only presenting sign of intravascular large B-cell lymphoma has been reported.\textsuperscript{177-178} Histologically, dilated blood vessels in the dermis and subcutis are filled and often extended by a proliferation of large neoplastic B-cells. These cells may cause vascular occlusion of venules, capillaries and arterioles. In some cases small numbers of tumor cells can also be observed around blood vessels. Multiagent chemotherapy is the preferred mode of treatment, also in patients presenting with skin-limited disease.\textsuperscript{176}

CONCLUSIONS AND FUTURE DIRECTIONS

The WHO-EORTC classification for cutaneous lymphomas presented herein may be considered as an important step forward. First, the development of this consensus classification will put an end to the ongoing discussion whether the EORTC or the WHO scheme can best be used, and is expected to contribute to a more uniform diagnosis and hence a more uniform treatment of patients with a cutaneous lymphoma. Second, major progress has been made in a better definition of some controversial groups of cutaneous lymphoma, in particular the group of PCFCL/PCLBCL and the group of CTCL other than MF, SS and the group of primary cutaneous CD30+ LPD. The new definitions of the group of PCFCL and PCLBCL, leg type and PCLBCL, other will allow a more reliable distinction between indolent and more aggressive types of CBCL, and facilitate the decision whether radiotherapy or systemic chemotherapy should be selected as first choice of treatment. Large multicenter studies are now required to validate the current proposals, and in
particular to investigate the diagnostic and prognostic value of bcl-2 and Mum-1/IRF4 protein expression.

The classification of CTCL other than MF, SS and the group of primary cutaneous CD30-positive LPD is still difficult, as it requires accurate clinicopathologic correlation and a number of complementary techniques to arrive at a definite diagnosis. SPTL (with an alpha/beta phenotype), extranodal NK/T-cell lymphoma, nasal type and CD4+/CD56+ hematodermic neoplasm are now fairly well-defined. However, considerable overlap is noted between cutaneous (and mucosal) GD-TCL and aggressive epidermotropic CD8+ CTCL. The similarities in clinical presentation and pattern of dissemination between these conditions may reflect similarities in homing profile and biologic function of normal gamma/delta-positive T-cells and activated CD8-positive cytotoxic T-cells, respectively. Apart from the group of SPTL and the group of CD4+ small/medium-sized pleomorphic CTCL these rare types of CTCL have a very poor prognosis and are generally resistant to conventional chemotherapy. More aggressive regimens, including allogeneic bone marrow transplantation, for patients with aggressive types of CTCL including advanced stages of MF and SS are currently under investigation. 179, 180

Recently, studies have started to investigate gene and protein expression profiles in different types of cutaneous lymphoma. It is expected that these studies will not only contribute to a better understanding of the molecular pathways involved in the development and progression of these lymphomas, but will also provide new molecular targets for diagnosis and therapeutic intervention, and ultimately to more refined classification schemes.

LEGENDS TO FIGURES

Figure 1. Mycosis fungoides
(A) Typical patches and plaques on the trunk.
(B) Infiltration of atypical T-cells into the epidermis with formation of Pautrier’s micro-abscess (H&E, original magnification, x 200)

Figure 2. Follicular mycosis fungoides
(A) Infiltrated plaques on the forehead and right eyebrow showing hair loss.
(B) Diffuse dermal infiltrate surrounding follicular structures. Note infiltrate-free zone beneath epidermis (no epidermotropism) (H&E, original magnification, x 25).

Figure 3. Primary cutaneous CD30-positive lymphoproliferative disease (pcCD30+ LPD).
(A) Diffuse dermal infiltrate of large atypical cells admixed with small lymphocytes. (H&E, original magnification, x 300).
(B) The large atypical cells are strongly positive for CD30.
(C-D) The histologic picture in A and B can be found both in C-ALC and in LyP. The final diagnosis depends on the clinical presentation. In combination with the solitary tumor of the patients shown in (C) the definite diagnosis will be C-ALC; in combination with recurrent, self-healing papulonecrotic skin lesions (D), the final diagnosis is LyP.

Figure 4. Subcutaneous panniculitis-like T-cell lymphoma
(A) Deeply seated nodular skin lesions and residual lipodystrophy after disappearance of the skin lesions.
(B) Infiltrates are almost exclusively localized in subcutaneous tissue resembling a lobular panniculitis (H&E, original magnification, x 25)
(C) Rimming of individual fat cells by neoplastic T-cells (H&E, original magnification, x 480)
(D) Tumor cells show positive staining for CD8.

Figure 5. Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma.
(A) Typical presentation with nodules and tumors showing central ulceration.
(B-D) tumor cells show striking epidermotropism (H&E, original magnification, x 150), and strongly express CD8 (C) and TIA-1 (D).
Figure 6. Primary cutaneous CD4-positive small/medium-sized pleomorphic T-cell lymphoma
(A) Presentation with a solitary tumor on the scalp.
(B) Diffuse dermal infiltrate mainly composed of small pleomorphic T-cells with few scattered blasts cells. (H&E, original magnification, x 750)

Figure 7. CD4+/CD56+ haematodermic neoplasm (blastic NK cell lymphoma)
(A) Presentation with large tumor on the back.
(B) Monotonous infiltration of medium-sized tumor cells (H&E; original magnification, x480)
(C) The tumor cells strongly express CD56.

Figure 8. Primary cutaneous marginal zone lymphoma
Characteristic clinical presentation with multiple nodules and small tumors on the back and arms.

Figure 9. Primary cutaneous follicle center lymphoma
(A) Typical presentation with tumors on the chest surrounded by less infiltrated erythematous skin lesions.
(B) Presentation with multiple tumors confined to the scalp.
(C) Diffuse dermal infiltrate mainly consisting of large centrocytes and multilobated cells (H&E, original magnification, x 480).
(D-E) Serial sections stained for CD20 (D) and bcl-2 (E). Bcl-2 is expressed by perivascular T-cells, but not by the neoplastic B-cells.

Figure 10. Primary cutaneous diffuse large B-cell lymphoma, leg type
(A) Clinical presentation with multiple tumors on right lower leg.
(B) Monotonous proliferation of centroblasts and immunoblasts (H&E, original magnification, x 480)
(C-D) Characteristically, the neoplastic B-cells strongly express bcl-2 (C) and Mum-1/IRF-4 (D).
