ABSTRACT

Cystic fibrosis (CF) is caused by a mutation of the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR). We examined platelet function in CF patients because lung inflammation is part of this disease and platelets contribute to inflammation. CF patients had increased circulating leukocyte-platelet aggregates and increased platelet responsiveness to agonists compared to normal controls. CF plasma caused activation of normal and CF platelets; however, activation was greater in CF platelets. Furthermore, washed CF platelets also showed increased reactivity to agonists. CF platelet hyperreactivity was incompletely inhibited by PGE$_1$. As demonstrated by Western blotting and RT-PCR, there was neither CFTR nor CFTR-specific mRNA in normal platelets. There were abnormalities in the fatty acid composition of membrane fractions of CF platelets. In summary, CF patients have an increase in circulating activated platelets and platelet reactivity, as determined by monocyte-platelet aggregation, neutrophil-platelet aggregation, and platelet surface P-selectin. This increased platelet activation in CF is the result of both a plasma factor(s) and an intrinsic platelet mechanism via cAMP/adenylate cyclase, but not via platelet CFTR. Our findings may account, at least in part, for the beneficial effects of ibuprofen in CF.
INTRODUCTION

Cystic fibrosis (CF) is the most common lethal genetic disease in Caucasians, affecting approximately 1 in 2,500 live births.\(^1\) In 1989 Tsui, Collins, Riordan and co-workers identified the genetic mutation responsible for CF and cloned its protein product which is called the cystic fibrosis transmembrane conductance regulator (CFTR).\(^2-4\) CFTR is a member of the ATP-binding cassette family of transporters and acts chiefly as a chloride channel, although it has various other functions including regulation of alternate chloride channels and epithelial sodium channels, and transport of ATP.\(^5-7\)

Defects in CFTR cause reduced chloride secretion into airways and enhanced sodium reabsorption, thereby resulting in dehydrated airway secretions, poor mucociliary clearance, and airway obstruction.\(^1\) Obstruction of the airways, along with poorly understood altered host defense mechanisms and an enhanced inflammatory response, leads to chronic airways infection and inflammation. This, in turn, causes an influx of polymorphonuclear cells which, when they become senescent and release their DNA into the airway mucous, contribute to thickening of airway secretions.\(^8\) The self-perpetuating cycle of obstruction, infection, and inflammation eventually causes pulmonary parenchymal destruction and respiratory failure. The life expectancy for CF patients in the United States is currently approximately 33 years.\(^9\)

Previous studies have shown that CF patients have increased \textit{ex vivo} platelet aggregability, increased release of thromboxane (TX)A\(_2\),\(^10-12\) and a blunted response to
prostaglandin (PG) E1-induced inhibition of platelet aggregation.\textsuperscript{13,14} Platelets contain or generate many inflammatory mediators including TXA\textsubscript{2}, platelet activating factor (PAF), RANTES (regulated upon activation, normal T-cell expressed and presumably secreted), histamine, serotonin, soluble CD40 ligand (sCD40L), and growth factors.\textsuperscript{15} These mediators are released upon platelet activation and have been associated with inflammatory lung disease in asthma.\textsuperscript{16} Therefore, endogenous platelet activation with release of pro-inflammatory mediators could play an important role in the pathogenesis of CF lung disease and a greater understanding of this mechanism could lead to novel clinical interventions. Significantly, anti-inflammatory agents known to inhibit production and release of platelet-derived inflammatory mediators slow the progression of lung disease in CF.\textsuperscript{17}

In this study, we attempted to further elucidate platelet function in CF and to determine if the abnormalities were due to a plasma factor or were an intrinsic property of CF platelets. In addition, we looked for both CFTR protein and CFTR mRNA in platelets to determine whether the underlying CF defect in chloride channel function could account for the platelet abnormalities. Finally, lipid fractions of CF and control platelets were examined because we have previously demonstrated that CFTR-expressing tissue from patients with CF has an imbalance in long chain polyunsaturated fatty acids with an excess of arachidonic acid (AA, a precursor to pro-inflammatory mediators) and a paucity of docosahexaenoic acid (DHA, a precursor to anti-inflammatory mediators);\textsuperscript{18} such a fatty acid imbalance in CF platelets could contribute to their hyperreactivity.
METHODS

Patient Enrollment

CF patients and normal control subjects were enrolled in this study. This study was approved by UMass Medical School’s Committee for the Protection of Human Subjects in Research (IRB), Worcester, MA. IRB approved, written, informed consent was obtained for all CF patients and normal control subjects. All CF patients included in the study met the CF Foundation Consensus Statement requirements for the diagnosis of CF.19 Patients were either outpatients in their usual state of health or inpatients receiving care for an exacerbation of their CF (Table 1). Hospitalized patients had blood drawn within 24 – 48 hours of admission to limit treatment effect from antibiotics or diet changes. Only one patient was receiving steroid therapy at the time of the study (Patient # 11, Table 1). Clinical information regarding genotype, pulmonary function and vitamin E status of the CF patients is shown in Table 1. Neither patients nor controls ingested anti-platelet medication (including aspirin and other non-steroidal anti-inflammatory drugs) for 10 days prior to blood collection. Where appropriate, ABO and Rhesus D (RhD) blood groups of the control subjects were matched to the relevant CF patients.

Comparison of circulating activated platelets and platelet reactivity between CF patients and normal controls

Circulating activated platelets and platelet reactivity in CF patients and normal control subjects were compared by whole blood flow cytometric detection of monocyte-platelet aggregates and neutrophil-platelet aggregates.20,21 Blood samples were obtained via
venipuncture from CF patients (n=18) and normal controls (n=18) by mixing 9 parts whole blood with 1 part 0.105 M (3.2%) trisodium citrate. Samples were assayed within 15 minutes. Microfuge tubes were prepared containing a mixture of HEPES-Tyrode’s buffer (10 mM HEPES, 137 mM sodium chloride, 2.8 mM potassium chloride, 1 mM magnesium chloride, 12 mM sodium carbonate, 0.4 mM sodium phosphate, 5.5 mM glucose, 0.35% w/v bovine serum albumin, pH 7.4), fluorescein isothiocyanate (FITC)-conjugated anti-CD14 (TÜK4, DAKO), phycoerythrin (PE)-conjugated anti-CD41 (5B12, DAKO), and platelet agonist. The blood sample was added to this reaction mixture and incubated at room temperature for 15 minutes. Final concentrations of agonists in the reaction mixture were 1.5 µM of thrombin receptor activating peptide (TRAP), 0.5 or 20 µM of adenosine diphosphate (ADP), or no agonist (HEPES-Tyrode’s buffer). After incubation, samples were fixed and erythrocytes lysed by FACS lysing solution (Becton Dickinson). Samples were analyzed in a FACSCalibur (Becton Dickinson) flow cytometer. Monocytes and neutrophils were identified by light scatter properties and differential expression of CD14. Staining with an irrelevant PE-conjugated mouse immunoglobulin (mouse IgG1-RPE, DAKO) was used to set a marker to identify platelet CD41-positive leukocytes. Expression of platelet-specific CD41 on the surface of the leukocytes indicated the formation of monocyte-platelet aggregates or neutrophil-platelet aggregates. The percentage of monocyte-platelet aggregates and neutrophil-platelet aggregates in circulating blood (i.e., no exogenously added agonist) and the reactivity of platelets to TRAP and ADP was compared for CF patients and normal controls by unpaired t tests.
Activation and reactivity of normal donor and CF platelets by CF plasma

To determine if platelet activation occurred secondary to a CF plasma constituent or as a result of an intrinsic CF platelet hyperreactivity, a plasma cross-over experiment was conducted and platelet activation and reactivity assessed by monocyte- and neutrophil-platelet aggregation using whole blood flow cytometry.\textsuperscript{20,21} Blood from CF patients and ABO RhD matched control subjects (n=6 pairs) was drawn into 3.2% citrate vacuum tubes. Citrated plasma was obtained by centrifugation at 1700 g for 15 minutes at room temperature. One hundred and twenty µL of citrated whole blood from normal controls was incubated with 420 µL of normal or CF plasma and then, in a parallel experiment, 120 µL of citrated whole blood from CF patients was incubated with 420 µL of normal or CF plasma for 20 minutes at room temperature. In analogous experiments, 420 µL of normal plasma was used to resuspend Mead acid (20:3, n-9) at three concentrations (1, 5, or 25 µM), that were then mixed with autologous whole blood 120 µL and incubated for 30 min at room temperature to determine if incorporation of this fatty acid into non-CF platelets affected formation of heterotypic aggregates (n = 6). Aliquots of each mixture were added to a reaction mix consisting of FITC-conjugated anti-CD14 (TÜK4), PE-conjugated anti-CD41 (5B12), and agonist. Final concentrations of agonists in the reaction mixture were 4 or 20 µM ADP, and 3 µM TRAP. Samples were fixed, lysed and analyzed for monocyte- and neutrophil platelet aggregates as described above. Matched pair-wise comparison of means for each mixture for each agonist was achieved using two-sided, paired t tests.
Activation and reactivity of washed normal donor and CF platelets

In order to assess the activation and reactivity of CF platelets without the influence of plasma constituents, P-selectin expression on washed platelet preparations was determined by flow cytometry.\textsuperscript{21-24} Washed platelet preparations of CF patients (n=4) and normal controls (n=4) were prepared using established methods.\textsuperscript{22,25} Briefly, platelet-rich plasma (PRP) was prepared by centrifugation of 3.2% citrated blood samples at 150 g for 15 minutes at room temperature. PRP was added to citrate wash buffer (11 mM glucose, 128 mM sodium chloride, 4.3 mM sodium phosphate monobasic, 7.5 mM sodium phosphate, 4.8 mM sodium citrate, 2.4 mM citric acid, 0.35% w/v bovine serum albumin, pH 6.5) containing apyrase VII (Sigma, 1.2 U/mL) and PGE\textsubscript{1} (Cayman Chemical, 300 ng/mL) and the mixture was centrifuged at 1,200 g for 10 minutes at room temperature. The platelet pellet was resuspended in this buffer and washed twice more. The resulting platelet pellet was resuspended at $1.5 \times 10^8$/mL in HEPES-Tyrode’s buffer without apyrase or PGE\textsubscript{1}. Platelets were activated with ADP (final concentrations 0, 1.25, 2.5, 5, 10, and 20 µM) for 30 minutes at room temperature, fixed, and analyzed for surface P-selectin expression using flow cytometry.\textsuperscript{22} Platelets were identified by light scatter characteristics and the binding of an FITC-conjugated CD61-specific monoclonal antibody (Y251, DAKO). Non-specific binding was determined using isotype matched RPE-conjugated MIgG\textsubscript{2a} (DAKO) and the expression of P-selectin on platelets was then quantified by the binding of PE-conjugated anti-CD62P monoclonal antibody (1E3, DAKO) to the platelet surface. For each agonist concentration, platelet mean P-selectin fluorescence and percentage of platelets positive for P-selectin expression were compared between CF patients and normal controls by unpaired t tests.
Ibuprofen and PGE₁ inhibition by of CF platelet activation

Citrated whole blood from CF patients and normal donor controls (n=7) was pre-incubated ex vivo with and without PGE₁ (100 nM and 1 µM). The samples were then activated with 20 µM TRAP or 20 µM ADP. In other experiments, whole blood (n=5) was pre-incubated with 50 µg/mL ibuprofen and stimulated with TRAP and ADP as above, 20 µM U46619 (a thromboxane A₂ analog), or 250 µg/mL arachidonic acid. Both ibuprofen and PGE₁ treated samples were analyzed for P-selectin expression as described above.

Measurement of Platelet Arachidonic Acid Release and Thromboxane A₂ Production

Washed platelets from CF (n = 4) and normal donor (n = 4) blood were labeled with [³H]-arachidonic acid (0.5 µCi/2 x 10⁹ platelets/mL, 65.9 Ci/mmol, Perkin Elmer Life and Analytical Sciences, Boston, MA) as previously described.²⁶ Platelet samples were resuspended in HEPES-Tyrode’s buffer, pH 7.4, and stimulated for 2 minutes with buffer or TRAP (20 µM) and the supernatants mixed with butylated hydroxytoluene (BHT) (50 mg/mL, 3 µL BHT/400 µL sample) and citric acid (1 mol/L, 60 µL/sample), then frozen until analysis. Lipids were extracted and analyzed by thin layer chromatography with TXB₂ (10 µL of 1 mg/mL stock in ethanol) (Biomol International, Plymouth Meeting, PA) as a standard.²⁷
**Analysis of Platelets for CFTR Protein and mRNA**

The expression of the CFTR protein in platelets and platelet membranes was determined by Western blot analysis. Washed platelets from both CF patients (n=2) and normal control subjects (n=2) were prepared with and without cell surface biotinylation. The blots were incubated with anti-CFTR antibodies (M3A7 and L12B4, Upstate Biotechnology) and developed. Canine cocker-spaniel kidney cells (MDCK-1) were used as a positive control. The presence or absence of CFTR mRNA in platelets, and as a positive control leukocytes, was determined by reverse transcriptase polymerase chain reaction (RT-PCR), using established methods. Total RNA was isolated and DNase treated before reverse transcription. Message from two control housekeeping genes (GADPH and β actin) were analyzed by real-time RT-PCR using reagent kits obtained from Applied Biosystems.

**Fatty Acid Analysis**

Washed platelet pellets were obtained from CF patients (n = 11) and normal control subjects (n = 10). Lipid fractions of platelets were extracted and methylated according to the method of Moser and Moser. Fatty acid methyl esters were quantified via gas chromatography-mass spectrometry as previously described. Total ion monitoring was performed and the mass of fatty acids was determined by comparing areas of unknown fatty acid methyl esters with a fixed concentration of internal standards. All specimens were analyzed in a blinded fashion and assay batches included platelet lipids from both
study groups. The concentrations of fatty acids between CF and normal controls were compared by unpaired \( t \) tests.

**Statistics**

Statistical comparisons were made using paired or unpaired \( t \)-tests as appropriate. Matched comparisons (e.g., before and after agonist on the same patient, normal blood with or without CF plasma added) were made using paired \( t \)-tests. Unmatched comparisons were made using unpaired \( t \)-tests.
RESULTS

Circulating Activated Platelets and Platelet Reactivity in CF

CF patients had increased circulating activated platelets compared with normal controls, as measured by both monocyte-platelet aggregates and neutrophil-platelet aggregates (Figure 1A and 1B, “no agonist”). Platelet activation, as determined by monocyte-platelet aggregates and neutrophil-platelet aggregates, was greater in CF patients compared with normal subjects following stimulation with 1.5 µM TRAP, 0.5 µM ADP and 20 µM ADP (Figure 1).

FIGURE 1
Figure 1: CF patients have increased circulating monocyte- and neutrophil-platelet aggregates and increased platelet responsiveness to ADP and TRAP compared with normal controls. Whole blood from CF patients and normal controls was incubated with or without agonist and analyzed for (A) monocyte-platelet aggregates and (B) neutrophil-platelet aggregates. Data are mean ± SEM, n=18. *p <0.05 vs. normal controls. †p <0.01 vs. normal controls.

Extrinsic vs. Intrinsic Platelet Defect

Monocyte-platelet and neutrophil-platelet aggregates in CF whole blood were higher after incubation with ABO/RhD-matched CF plasma than after incubation with normal plasma
(Figure 2A). Similarly, monocyte-platelet and neutrophil-platelet aggregates in normal whole blood were higher after incubation with ABO/RhD-matched CF plasma than after incubation with normal plasma (Figure 2B). Figure 2C compares the solid bars of figure 2A (CF plasma + CF whole blood) with the open bars of figure 2B (CF plasma + normal whole blood). Figure 2C demonstrates that when whole blood from CF and normal subjects was incubated in CF plasma, platelet activation (as determined by monocyte-platelet aggregates and neutrophil-platelet aggregates) was greater in CF blood than in normal blood. In summary, figure 2 demonstrates that CF plasma makes normal and CF platelets more reactive than does normal plasma (figures 2A and 2B), but that CF platelets are more reactive than control platelets irrespective of the plasma milieu (figure 2C).

FIGURE 2
Figure 2: **CF plasma causes activation of normal and CF platelets.** (A) Monocyte- and neutrophil-platelet aggregates in CF whole blood after incubation in ABO/RhD-matched CF or normal control plasma. (B) Monocyte- and neutrophil-platelet aggregates in normal whole blood after incubation in ABO/RhD-matched CF or normal control plasma. (C) Comparison of the solid bars of figure 2A (CF plasma + CF whole blood) with the open bars of figure 2B (CF plasma + normal whole blood). Figure 2C demonstrates that when whole blood from CF and normal subjects was incubated in CF plasma, platelet activation (as determined by monocyte-platelet and neutrophil-platelet aggregates) was greater in CF
blood than in normal blood. Data are mean ± SEM, n=6. *p <0.05 vs. normal plasma or whole blood.

In whole blood from normal control subjects, monocyte- and neutrophil-platelet aggregates were greater when incubated with ABO/RhD-matched CF plasma than when incubated with normal plasma, after stimulation with 4 μM ADP, 20 μM ADP and 3 μM TRAP (Figure 3A).

Similarly, in CF whole blood, monocyte- and neutrophil-platelet aggregates were greater when incubated with CF plasma than when incubated with ABO/RhD-matched normal plasma, after stimulation with 4 μM ADP, 20 μM ADP and 3 μM TRAP (Figure 3B). Thus, CF plasma increased the reactivity of both normal and CF platelets to ADP and TRAP.
Figure 3: **CF plasma increases the reactivity of normal and CF platelets to ADP and TRAP.** (A) Monocyte- and neutrophil-platelet aggregates in normal control whole blood incubated with CF plasma or ABO/RhD-matched normal plasma and then stimulated with agonist. (B) Monocyte- and neutrophil-platelet aggregates in CF whole blood incubated with CF plasma or ABO/RhD-matched normal plasma and then stimulated with agonist. Data are mean ± SEM, n=6.

*p <0.05 vs. normal plasma. †p <0.01 vs. normal plasma.

P-selectin expression of washed platelets was greater in CF patients than in normal control subjects after activation with various concentrations of ADP (Figure 4). Unstimulated P-selectin expression was slightly, though not significantly, greater in CF
platelets than controls (Figure 4). That washed, plasma-free CF platelets were more reactive to ADP than normal platelets, indicates that the hyperreactivity of CF platelets is due in part to an intrinsic platelet mechanism.

FIGURE 4

Figure 4: Washed CF platelets are more reactive to ADP than normal platelets as measured by P-selectin expression. Percentage of CF and normal washed platelets expressing P-selectin with and without stimulation by ADP. Data are mean ± SEM, n=4. *p <0.05 vs. normal platelets.
**Effects of PGE₁**

The elevated P-selectin expression after agonist stimulation of CF platelets was incompletely inhibited by 100 nM PGE₁ (Figure 5, solid bars). In contrast, normal platelets showed more complete inhibition of agonist-induced P-selectin expression with PGE₁ (Figure 5, hatched bars). There was no greater inhibition of P-selectin expression even when using concentrations of PGE₁ up to 1 µM. These results suggest that both increased cAMP levels and other factors are important in the increased platelet surface P-selectin expression in CF.

Effect of Ibuprofen on CF Platelet Function

Pre-treatment of CF platelets with 50 µg/mL of ibuprofen did not significantly decrease platelet surface P-selectin expression in response to stimulation with ADP or TRAP (data not shown). However, when arachidonic acid was used as the agonist, pre-treatment with ibuprofen markedly inhibited P-selectin expression, as would be expected. The platelet response to the stable TXA₂ analog U46619 was unaffected by pre-treatment with ibuprofen, verifying the presence of normal TXA₂ receptors on these cells.

CFTR Protein and mRNA Are Not Expressed in Platelets

CFTR protein was not detected in control or CF platelet lysates or biotinylated platelet membrane fractions using Western blot analysis, but was seen in the control MDCK whole cell lysate. CFTR mRNA was not detected in platelet preparations from normal controls. CFTR message was detected in the leukocyte positive control samples as expected. The mRNA of two housekeeping genes (GADPH and β-actin) was detected in all platelet samples, confirming the integrity of the platelet RNA.

Platelet Fatty Acid Content

Analysis of washed platelet pellets for fatty acid pools showed a significant increase in 20:3 n-9 (Mead acid) levels in CF platelets compared with normal control subject platelets (p=0.017, Figure 6) and plasma (p=0.006, not shown). There was also an increase in 22:5 n-6 in CF platelets compared to normal controls (p=0.012) (Figure 6). However, CF platelets were not significantly different from control platelets with regard to concentrations of AA (20:4 n-6), DHA (22:6 n-3), and the AA/DHA ratio (Figure 6).
FIGURE 6

![Bar graph showing nmol / 10^9 platelets for CF Patients and Normal Controls.](image-url)
Figure 6: There is no difference between CF and control platelets with regard to arachidonic acid (AA), docosahexaenoic acid (DHA), or their ratio (6A and 6B); however, CF platelets have increased Mead acid (20:3 n-9) and 22:5 n-6 fatty acid concentrations compared to control platelets (6C). Data are mean ± SEM, n = 11 CF patients and n = 10 normal controls. *p <0.05 vs. controls platelets.

Arachidonic Acid Release and Mead Acid Effect

Not only was total AA not different between CF and control platelets (Figure 6), there was no difference in AA release or synthesis of the AA metabolite TXA2 as demonstrated by use of [3H]-AA (results not shown). Addition of Mead acid (20:3, n-9) to normal platelets did not increase the formation of monocyte-platelet or neutrophil-platelet aggregates (results not shown).

No Correlation Between Platelet Activation and Vitamin E Status or Pulmonary Function

There was no correlation between any of the measurements of platelet activation and vitamin E status or pulmonary function as measured by the percent of predicted of the forced expiratory volume in the first one second of expiration (FEV1%) in the CF patients.
DISCUSSION

The conclusions of this study are: 1) CF patients have an increase in circulating activated platelets and platelet reactivity, as determined by monocyte-platelet aggregation, neutrophil-platelet aggregation, and platelet surface P-selectin; 2) This increased platelet activation in CF is the result of both a plasma factor(s) and an intrinsic platelet mechanism via cAMP/adenylate cyclase (as evidenced by the results with PGE1), but not via platelet CFTR.

In this study, we demonstrated that CF patients have increased numbers of circulating activated platelets compared to normal control subjects, as measured by monocyte-platelet and neutrophil-platelet aggregates (Figure 1). We have previously demonstrated that these heterotypic aggregates are very sensitive markers of platelet activation.32 In addition, whole blood studies showed that CF platelets had greater aggregability with monocytes and neutrophils in response to agonists than did control platelets (Figure 1). CF plasma caused activation of normal and CF platelets (Figure 2), but the activation was greater in the CF platelets than in normal platelets. CF plasma also increased the reactivity of normal and CF platelets to ADP and TRAP (Figure 3). Furthermore, there was an increased surface expression of P-selectin in CF washed platelet preparations compared with washed normal platelets (Figure 4). Taken together, these experiments demonstrate that the increased platelet activation in CF is the result of both an intrinsic platelet mechanism and plasma factors. Even in well, young CF patients with normal pulmonary function there is an abnormality in platelet function. Our findings are
consistent with previous work which has shown increased platelet aggregation and/or markers of platelet activation in CF patients.\textsuperscript{10-12,33-35} Thus, excessive platelet activation is present in CF and may contribute significantly to the lung disease seen in this disorder.

Interestingly, our results do not support the earlier findings of increased TXA\textsubscript{2} release from CF platelets.\textsuperscript{10} The finding of increased urinary TXB\textsubscript{2} by Ciabottoni et al\textsuperscript{11} would support a hypothesis that platelet activation contributes directly to lung damage. The results of our study suggest that there is a source other than platelets for the urinary thromboxane, as has been previously suggested.\textsuperscript{36} However, we did confirm that the platelets from CF patients are hyperreactive compared to control platelets. The metabolic basis and downstream consequences of the platelet hyperreactivity remain to be elucidated.

Others\textsuperscript{13,14} have shown an incomplete inhibition of platelet aggregation by PGE\textsubscript{1} and we observed a decreased response to PGE\textsubscript{1} inhibition of surface P-selectin expression in CF as compared to control platelets. An absence of the cAMP-regulated chloride channel, CFTR, in CF platelets could explain these findings. However, we found neither message for CFTR nor CFTR protein itself in normal donor platelets. Therefore, the intrinsic abnormality in CF platelets must be due to a non-CFTR cAMP-regulated platelet chloride channel or to a CFTR-related abnormality that is expressed in megakaryocytes but not in platelets.
We have reported abnormalities in fatty acids in CFTR expressing tissue which could affect inflammation in CF patients; that is, epithelial cells have an abnormal ratio of omega-6 to omega-3 fatty acids, specifically an increase in the AA/DHA ratio.\(^{18}\) Such an imbalance could lead to an increase in pro-inflammatory derivatives of AA and a paucity of anti-inflammatory DHA metabolites.\(^{37}\) Consistent with our inability to find evidence of CFTR expression in platelets, however, platelets from CF patients did not differ significantly from control platelets with regard to AA or DHA (Fig. 6). Thus, we cannot ascribe the increased intrinsic platelet reactivity in CF to an abnormality in platelet AA/DHA balance. However, this imbalance is present in plasma\(^{18,38}\) and could lead to platelet activation from increased circulating AA metabolites (consistent with the previously reported increased urinary thromboxane in CF\(^{11}\)). Recently, CF patients and CF knockout mice have been shown to be deficient in the anti-inflammatory lipoxin family of mediators.\(^{39}\) The proposed imbalance in CF pro- and anti-inflammatory mediators could favor platelet activation, even if the platelets themselves do not intrinsically release excess thromboxane.

Further fatty acid analysis revealed an increase in the terminal n-6 fatty acid (22:5 n-6) in CF platelets (Figure 6). Accumulation of this long chain, polyunsaturated fatty acid may competitively inhibit the generation of DHA at the level of the DHA-precursor, 22:5 n-3. We also observed an increase in Mead acid (20:3 n-9), in CF platelets (figure 6) and plasma (not shown). Legarde et al.\(^{40}\) showed that Mead acid is metabolized by a platelet-derived lipoxygenase to an end-product with PGE\(_2\)-like activity which enhances platelet aggregation and that loading normal platelets with Mead acid enhances their
aggregability. However, when we incubated platelets with three different concentrations of Mead acid in the presence or absence of a platelet agonist, we did not observe any increase in whole blood heterotypic aggregates. In summary, an intrinsic fatty acid abnormality is present in CF platelets and it is possible that the increase in platelet activation observed is due to a manifestation of this abnormality, but excess Mead acid alone does not lead to increased platelet-leukocyte aggregates.

There are a number of potential plasma-mediated explanations for platelet hyperreactivity in CF. As mentioned above, the imbalance in omega-3 and omega-6 fatty acids seen in CF serum may favor inflammation, as may an increase in plasma levels of sCD40L. In addition, approximately 90% of CF patients have pancreatic insufficiency and are at risk for malabsorption of fat soluble vitamins leading some to postulate a relationship between low levels of the antioxidant vitamin E and increased platelet activation. Our results do not support the concept that increased platelet activation in CF is a consequence of a nutritional depletion of vitamin E as we saw no correlation between vitamin E status and platelet activation. There are other oxidant stresses in CF (including a purported depletion of glutathione, an increase in reactive oxygen species from neutrophils, and generation of isoprostanes from long chain polyunsaturated fatty acids by the action of H$_2$O$_2$) that may contribute to platelet activation.

CFTR dysfunction, as seen in CF, has been associated with an elevation in plasma ATP. On balance, ATP is probably an agonist of platelet aggregation and activation in vivo. Thus, increased platelet activation may be a direct consequence of the basic molecular
defect in CFTR due to disturbances in fatty acid metabolism or due to increased plasma ATP concentrations even though CFTR is not expressed in platelets.

The pulmonary inflammatory response in CF patients is exaggerated compared with normal individuals, with evidence of airway inflammation as early as 4 weeks of age. Konstan et al. showed that high dose ibuprofen led to a slowing of the loss of lung function when used over 4 years in CF patients. Serum levels of ibuprofen in this study were high enough to inhibit the migration, adherence, swelling and aggregation of neutrophils. Many CF clinicians have avoided using such high doses of ibuprofen because of the need to monitor serum levels of the drug and because of concerns about the potential adverse effects of this high dose regimen. Thus, in 2003 only about 5% of patients cared for at CF Foundation accredited centers received high dose ibuprofen. If the benefit observed in the NSAID study of CF patients was due, even in part, to inhibition of platelet activation rather than decreased neutrophil function, then a lower dose regimen of NSAID might be effective and would be more appealing to clinicians and patients. Furthermore, aspirin and/or clopidogrel, which are stronger antiplatelet drugs than NSAIDs, may have greater beneficial effects than NSAIDs in patients with CF.

Acknowledgments: We thank Bruce Stanton, PhD and Bonnie Courtemarsh (Dartmouth Medical School) for performing Western blot analysis of platelets for CFTR protein, Joanne Cluette-Brown (Massachusetts General Hospital) for fatty acid analysis of platelets and Lori Krueger for assistance in platelet function studies.

</tbody>
</table>

1. Measured as alpha-tocopherol. Lower limit of normal = 5.5 mg/L
2. Normal: 80 – 120% of predicted
3. Outpatient = seen for routine CF Clinic visit; Inpatient = hospitalized for therapy of an exacerbation of CF
4. Studies done on each subject’s platelets: a = leukocyte-platelet aggregates (figure 1); b = whole blood studies (figures 2 & 3); c = washed platelet - P-selectin measurements (fig 4); d = inhibition of P-selectin expression by PGE\(_1\) (figure 5); e = measurement of fatty acids (figures 6); f = AA and thromboxane release.

unk = unknown

Advance online articles have been peer reviewed and accepted for publication but have not yet appeared in the paper journal (edited, typeset versions may be posted when available prior to final publication). Advance online articles are citable and establish publication priority; they are indexed by PubMed from initial publication. Citations to Advance online articles must include digital object identifier (DOIs) and date of initial publication.
