THE INCIDENCE OF HEPARIN-INDUCED THROMBOCYTOPENIA
IN MEDICAL PATIENTS TREATED WITH
LOW MOLECULAR WEIGHT HEPARIN
A prospective cohort study

Summary

In contrast with extensive documentation in patients treated with unfractionated heparin (UFH), the incidence of heparin-induced thrombocytopenia (HIT) in medical patients receiving low-molecular-weight heparin (LMWH) is less well defined. In a prospective cohort study, the platelet count was monitored in 1754 consecutive patients referred to 17 medical centers and treated with LMWH for prophylaxis or treatment of thromboembolic disorders. The diagnosis of HIT was accepted in case of a platelet drop > 50%, the absence of obvious explanations for thrombocytopenia, and the demonstration of heparin-dependent IgG antibodies. HIT developed in 14 patients (0.80%; 95% CI, 0.43-1.34), in all of them within the first two weeks, and was more frequent in patients who had (1.7%) than in those who had not (0.3%) been exposed to UFH or LMWH (OR=4.9; 95% CI, 1.5-15.7). The prevalence of thromboembolic complications in HIT patients (4/14, 28.6%) was remarkably higher than that (41/1740, 2.4%) observed in the remaining patients (OR=16.6; 95% CI, 5.0-55.0). Immune thrombocytopenia and related thromboembolism may complicate the clinical course of medical patients treated with LMWH with a frequency that is not different from that observed with the use of UFH. The previous administration of heparin increases the rate of HIT.
Introduction

While the incidence of heparin-induced thrombocytopenia (HIT) and its clinical features have been thoroughly investigated in patients treated with unfractionated heparin (UFH) (1-4), much lower attention has been paid to the risk of this threatening complication of heparin treatment in patients receiving low-molecular-weight heparin (LMWH). Indeed, the risk of this immune disorder from LMWH prophylaxis or treatment is generally reputed to be much lower than that observed with the use of UFH (1-4), although cases of HIT are occasionally encountered in clinical practice. Accordingly, there is an increasing tendency to withhold platelet surveillance from medical patients treated with prophylactic or therapeutic doses of LMWH, especially outside hospital departments (1).

To our knowledge, only limited information on the rate of HIT in patients receiving LMWH is available. In two prospective controlled studies, addressing the rate of HIT in patients randomized to UFH or LMWH for prevention (5) and treatment (6) of deep vein thrombosis (DVT), respectively, clinical and/or laboratory evidence of HIT was found in patients treated with LMWH to a significantly lower extent than in those who received UFH. Although this information is reassuring, there is the need for more extensive information coming from cohort studies in order to better quantify the true rate of immune thrombocytopenia and HIT-related complications in different settings of patients treated with LMWH.

In order to estimate the incidence and timing of HIT in medical patients requiring the administration of LMWH for various indications either in hospital or at home, we performed a multicentre prospective cohort study in 1754 consecutive patients referred to 17 departments of Internal Medicine. All patients recruited for this investigation were followed for the occurrence of HIT and overt thromboembolic events.
Methods

Study Design

This was a prospective cohort multicentre study specifically designed to determine the incidence of HIT in both hospitalized and non-hospitalized medical patients receiving LMWH, as well as the occurrence of arterial or venous thrombotic events related to this complication. The study was conducted according to the ethical principles stated in the Declaration of Helsinki, and the protocol was approved by the Institutional Review Board of each participating centre.

Inception Cohort

Consecutive patients referred to 17 Departments of Internal Medicine between March 2003 and September 2004 were eligible for the study provided that they had indication to receive subcutaneous LMWH for prophylaxis or treatment of arterial or venous thromboembolic diseases. Patients who were already on UFH or LMWH at referral were excluded, as were those who had an abnormal baseline platelet count (lower than 150 x 10^9/L or higher than 450 x 10^9/L), had hematological malignancies, were receiving radio- or chemo-therapy, had clinical or laboratory findings compatible with disseminated intravascular coagulation, sepsis, liver cirrhosis, hypersplenism, or severe renal insufficiency.

At referral, all patients included in the study received a thorough medical history and physical examination with particular attention to any previous (documented or likely) exposure to UFH or LMWH.

In patients requiring the prevention of thromboembolism, prophylactic doses of LMWH were programmed for variable periods of time, usually covering the entire period of risk. In patients with acute thromboembolic disorders, LMWH was administered in fixed therapeutic doses adjusted to body weight, with oral anticoagulation started in the first week of treatment, and heparin interrupted when
the International Normalized Ratio reached a value $\geq 2.0$ in two consecutive determinations. In a minority of patients a longer course of LMWH, not followed by oral anticoagulants was programmed.

Doses and duration of prophylactic or therapeutic LMWH were left to discretion of attending physician.

**Development of HIT**

A platelet count was performed at baseline, and thereafter at least every two or three days. The diagnosis of HIT was suspected in all cases of platelet drop $\geq 50\%$ of pretreatment value, provided that this was confirmed by a second determination. In all patients in whom a likely explanation for thrombocytopenia (hemodilution from fluids/blood, sepsis, disseminated intravascular coagulation, other drug reactions, etc.) could not be found, a blood sample was obtained for the subsequent determination of heparin-dependent antibodies. The diagnosis of HIT was accepted in case of demonstration of heparin-dependent antibodies. In case of unexpected patient’s death precluding the laboratory determination, the diagnosis of HIT was accepted if there was no other obvious clinical explanation for thrombocytopenia, and the platelet drop had occurred at least five days after heparin start.

The first day of heparin use was calculated as day zero, and the day when a drop in the platelet count of at least 50% was observed was assumed to be the day of HIT occurrence.

All included patients underwent their laboratory and clinical observation for the entire duration of drug administration (plus an additional 3-day period), for a maximum of one month. In a subgroup of consecutive patients enrolled at three participating centres clinical information was obtained, along with a platelet count, one month after LMWH cessation in order to check the development of delayed HIT.
Laboratory determination of heparin-dependent IgG antibodies

Both an antigen and a functional assay were performed to detect heparin-dependent antibodies according to previously described methods (7-9). Blood samples were collected from a brachial vein with fine needle in sodium citrate 1:10 (antigen assay) and without anticoagulant (functional assay). Samples were then centrifuged at 10 000 g for 3 minutes and stored at −70°C.

The samples were screened by an antigen assay that detects antibody mixture of IgG, IgA, IgM antibodies against platelet factor 4 complexed with polyvinylsulfonate (Genetic Testing Institute, Brookfield, WI, USA) (7,8). Absorbance of the substrate of alkaline-phosphatase was measured at 405 nm. This test was followed, in case of a positive result, by the search for HIT antibodies of the IgG class using a single anti-IgG alkaline phosphatase conjugate Fc specific (Sigma Ch, USA). The cut-off value of optical density (OD) for the antibody determination was assessed using plasma samples of 43 patients who did not develop thrombocytopenia within 48 hours of LMWH start, and was found to be 0.4 for antibodies mixture, and 0.3 for IgG antibodies, respectively.

The functional test was done with a modification of the visual evaluation of heparin-induced platelet activation (HIPA) assay (9). Fresh blood was obtained from 3 donors with clinical history of HIT and collected into acid-citrate dextrose (1:5 vol:vol). Platelet-rich plasma (PRP) was separated by centrifugation at 150 g for 12 min, and apyrase 4U/ml (Sigma Chemical Company, St Louis, Mo) was added; after a centrifugation at 600 g, platelets were resuspended in calcium and albumin free Tyrode's buffer, pH 6.2 containing apyrase 2 U/ml. After a further centrifugation at 600g, platelets were resuspended to a final concentration of 250 x 10⁹/L in Tyrode's buffer, pH 7.4, containing 1 mM MgCl₂ and 2 mM CaCl₂. The test mixture consisted of 20µl of heat-inactivated patient serum, 10 µl of heparin 0.3 and 100 IU/ml
(Epsoclar, BIL, Novate Milanese, Italy) or buffer, and 70 µl of washed platelets. The test mixture was placed in the wells of a microtiter plate (Greiner, Nurtingen, FRG, Germany) containing two steel spheres, and agitated for 45 min at 25 °C in a magnetic stirrer (900 RPM). After stirring, the transparency of the suspension using low but not high heparin concentration was considered as a positive result. Platelets stimulated by 5 µM Ionophore A23187 (Sigma), and reference HIT serum giving positive result with a lag time of about 20 minutes, served as positive controls.

The laboratory determination was performed at either of two participating centres (Padua and Palermo), which adopted an identical approach.

**Thromboembolic complications**

The clinical suspicion of venous or arterial thromboembolism was confirmed by the following objective tests: compression ultrasound or venography in case of suspected deep-vein thrombosis, ventilation/perfusion lung scanning, spiral CT or pulmonary angiography in case of suspected pulmonary embolism, ECG with enzymatic support in case of suspected myocardial infarction, and cerebral CT scan or MRI in case of suspected stroke. In case of death, the cause was either investigated by autopsy or adjudicated according to the opinion of a physician unaware of the study aims.

**Analysis**

We evaluated the proportion, and its 95% confidence interval (CI), of patients who developed HIT among all those who were treated with LMWH.

Odds ratios (OR) and their 95% CI were used to describe the association between HIT and potential predisposing factors, and between thromboembolic complications and HIT. An OR was considered to be statistically significant when the lower limit of the 95% CI was >1.0.
The chi-square test was used to compare proportions; a P lower than 0.05 was considered to indicate a statistically significant difference.

Results

Patients

Out of 2403 eligible patients, 629 (26.2%) were excluded because of ongoing (LMW) heparin administration (n=240), abnormal platelet count at baseline (n=181), concomitant radio- or chemotherapy (n=84), hematological malignancies (n=48), liver cirrhosis (n=31), severe renal insufficiency (n=23), septicemia (n=12) or disseminated intravascular coagulation (n=10). Of the remaining 1774 patients, 20 did not agree to participate. Therefore, 1754 patients were included in the study, of whom 816 (46.5%) had LMWH treatment entirely in hospital, and the remaining 938 (53.5%) primarily on ambulatory basis.

The main demographic and clinical characteristics of study patients are shown in Table 1. Of the 1754 patients, 376 (21.4%) received prophylactic low-dose LMWH, 728 (41.5%) therapeutic doses adjusted to body weight, and the remaining 650 (37.1%) intermediate doses (either fixed or adjusted to body weight); 268 (15.3%) were affected by malignancy; 598 (34.1%) had previous administration of UFH or LMWH, including 60 who had received either drug in the previous three months; finally, 32 (1.8%) were pregnant patients.

The median duration of LMWH administration was 8 days (range, 2 to 30): 713 patients (40.6%) received up to 7 days of treatment, additional 712 patients (40.6%) up to 14, 142 (8.1%) up to 21, and the remaining 187 (10.7%) up to 30 days. Of the entire cohort 320 patients (18.2%), consecutively enrolled at three participating centres, had clinical and laboratory surveillance up to one month after LMWH discontinuation.
Heparin-induced thrombocytopenia: incidence, risk factors, and outcome

During the study period, 35 patients (2.0%) developed a platelet drop of at least 50%, confirmed by a second determination. In 4 patients, obvious explanations for thrombocytopenia could be found. Two other patients, both affected by advanced cancer, died unexpectedly because of myocardial infarction and pulmonary embolism occurring after 4 and 24 days, respectively, in timely association with their platelet drop. They could not receive the laboratory determination of heparin-dependent antibodies, therefore, the clinical suspicion of HIT could not be confirmed. However, in both patients a cancer-related disseminated intravascular coagulation at time of their fatal thromboembolic complication could not be excluded. Thus, these two patients were considered as unlikely to qualify for HIT development.

The antigen assay was positive in 14 of the 29 patients tested for the presence of heparin-dependent IgG antibodies, the OD being $>1.0$ in 12. The functional assay was positive in 11 of these 14 patients, and negative in the remaining 15. Hence, the rate of HIT in our cohort was $14/1754$ (0.80%; 95% CI, 0.43 to 1.34). If the two patients who died unexpectedly because of thromboembolic complications, and in whom the search for heparin-dependent antibodies could not be done, are included in the analysis, this rate increases to 0.91% (95% CI, 0.52 to 1.48). However, if among patients who underwent serological testing the three patients with negative functional tests are excluded, then the frequency falls to 0.63% (95% CI, 0.31 to 1.12).

The main features of the 14 HIT patients are shown in table 2. In all patients, the platelet drop begun or accelerated from the beginning of the fall onwards, without a preceding profile of a rising platelet count.

Of the 14 patients who developed HIT, 3 occurred in the 376 patients (0.8%) who received low-dose LMWH for prophylactic indications, 6 in the 728 patients (0.8%) who received full doses adjusted to body weight for therapeutic indications,
and the remaining 5 in the 650 patients (0.8%) who had intermediate doses of LMWH (non significant differences); 7 occurred in the 816 patients (0.9%) who had an inhospital LMWH treatment, and 7 in the 938 (0.7%) who were treated primarily at home (non significant difference). HIT developed in 9 of the 880 patients (1.0%) treated with nadroparin, in 3 of the 700 (0.4%) treated with enoxaparin, in 2 of the 64 (3.1%) treated with dalteparin, and in none of the 110 who were given reviparin or parnaparin.

The previous administration of heparin increased the rate of HIT. This complication indeed occurred in 10 of the 598 patients (1.7%) who had previous administration of UFH or LMWH (including 1 in the 60 patients who had received either drug in the previous three months), as compared to 4 of the 1156 patients (0.3%) who had never been exposed to (LMW)heparin (OR=4.9; 95% CI, 1.5 to 15.7). After excluding from the analysis the 60 patients who had recently been exposed to (LMW)heparin, the OR did not change. HIT developed in a slightly higher proportion of cancer (4/268, 1.5%) than non cancer patients (10/1486, 0.7%), however, the difference was not statistically significant (OR=2.2; 95% CI, 0.7 to 7.2). No cases of HIT were observed among the 32 pregnant patients. Finally, no cases of delayed HIT were observed among the 320 patients who had a prolonged clinical and laboratory observation (0%; 95% CI, 0 to 1.15%).

With the exception of the patient who had received a (LMW)heparin treatment less than three months earlier (35 days), and developed HIT on day 2, in all remaining patients HIT developed between day 4 and 13: in six patients between day 4 and 6, and in additional seven between day 7 and 13 of LMWH treatment.

The medical treatment of patients who developed HIT was left to discretion of attending physicians. Ten patients received the intravenous infusion of lepirudin, 2 were treated with danaparoid, and the remaining 2 patients with dermatan sulphate according to either manufacturers instructions (in case of treatment with lepirudin or
danaparoid) or evidence from available literature (in case of treatment with dermatan sulphate) (10). In all 14 patients platelet count normalized within 10 days after LMWH discontinuation.

**Symptomatic thromboembolic complications**

Four of the 14 patients (28.6%; 95% CI, 8.4 to 58.1) who developed HIT experienced clinically symptomatic thromboembolic complications in timely association with the occurrence of HIT (proximal DVT in 1, symptomatic extension of ipsilateral DVT in 1, transitory ischemic attack in 1, and stroke resulting in a leg paralysis in 1). All of them belonged to the group of those who had been previously exposed to heparin. Thromboembolic complications were recorded also in 41 of the 1740 patients (2.4%; 95% CI, 1.7 to 3.2) who did not develop HIT (venous thromboembolism in 16, ischemic stroke in 13, acute myocardial infarction in 10, arterial embolism in 2).

The incidence of thromboembolic events in patients who developed HIT was remarkably higher than that observed in patients who did not, leading to an OR of 16.6 (95% CI, 5.0 to 55.0). With the exception of the two patients described above, in no other patients belonging to the latter group did the platelet count decrease during or following the thromboembolic complication.

**Discussion**

As LMWHs are increasingly been used in the substitution for UFH for prophylaxis and treatment of venous and arterial thromboembolic disorders, there is the need to know the true frequency and severity of HIT occurring in medical patients who are candidates for the use of these compounds. In our study, specifically designed to assess the incidence of HIT in medical patients, we checked the development of this complication in 1754 consecutive patients referred to 17 medical departments who
were administered LMWH for variable periods of time for prophylactic or therapeutic indications. Of interest, in more than 50% of patients the treatment was conducted primarily on a home basis. Using stringent criteria, 14 patients (0.80%; 95% CI, 0.43 to 1.34) developed this complication. This rate is fully consistent with that (0.84%) recently found in a cohort of medical patients treated with UFH, in which similar criteria for HIT detection were adopted (11). Accordingly, this threatening and potentially fatal complication is to be expected in medical patients treated with LMWH as frequently as in those treated with UFH.

As expected, the risk of thromboembolic complications in patients who developed HIT was high. Four out of the 14 (28.6%) HIT patients experienced either arterial or venous unexpected thromboembolic complications, as compared to 41 of the 1740 (2.4%) non-HIT patients, leading to an OR of 16.6 (95% CI, 5.0 to 55.0). The inclusion of the two patients who died unexpectedly because of thromboembolic complications in timely association with the platelet drop and in whom the diagnosis of HIT could not be certainly ruled out would have increased the OR (26.1; 95% CI, 9.1 to 75.5), and so would have the exclusion of the three patients with negative functional test for HIT antibodies (23.7; 95% CI, 6.7 to 84.2). Although the absolute rate was lower than that observed in our recent investigation conducted in medical patients treated with UFH (3/5, 60%) (11), the confidence intervals clearly overlap each other. Moreover, this frequency was far higher than that observed in the remaining patients of our cohort. Our data suggest that in those medical patients who develop immune HIT while on LMWH treatment, the occurrence of arterial or venous thromboembolic complications is to be expected as often as in patients treated with UFH.

Of interest, no difference in the rate of immune HIT could be detected between patients who had their LMWH treatment conducted entirely in hospital and those treated primarily on an ambulatory basis. Patients who received LMWH for
prevention of VTE were as likely to develop HIT and its thrombotic complications as were those who received LMWH for treatment of VTE and those who were given LMWH for prevention or treatment of cardiovascular or cerebrovascular events. Although a higher incidence of HIT was observed in patients treated with dalteparin and, to a smaller extent, with nadroparin than in those treated with enoxaparin, and no cases were observed in patients treated with reviparin or parnaparin, the lack of a randomized study design and the discrepancy in the number of patients treated with each compound do not allow to conclude that a true difference exists in the potential of the various LMWHs to produce immune thrombocytopenia. Anyway, based on our study results a difference cannot be excluded, and therefore further investigations are needed to clarify this potentially important issue. Of interest, no cases of HIT were observed among the 32 pregnant patients. These considerations suggest that routine platelet count monitoring for HIT is appropriate in all categories of medical patients candidate to LMWH treatment irrespective of setting, clinical indication, heparin type or dosage. Maybe pregnant patients might remain an important exception, as to our knowledge there has never been a well-documented case of HIT reported in a pregnant patient who was treated exclusively with LMWH (12).

Surprisingly enough, the incidence of HIT was significantly higher in patients who had a previous (documented or likely) exposure to either UFH or LMWH than in those who had never been exposed to heparin (OR=4.9; 95% CI, 1.5 to 15.7), even when the analysis was confined to the only patients who had been treated with (LMW)heparin more than three months earlier. These findings are in contrast with those from our recent investigation in medical patients treated with UFH (11), and may account for the relatively early occurrence of thrombocytopenia (day 4-6) in several patients of our cohort (see table 2). This potentially important issue needs to be confirmed by future investigations.

The temporal pattern of thrombocytopenia reproduced that already described
in medical patients treated with UFH (1,11). In all patients the platelet drop begun or accelerated from the beginning of the fall onwards, without a preceding profile of a rising platelet count. This makes the behavior of HIT in medical patients substantially different from that is usually seen in the surgical setting (1). As expected, in the only HIT patient who had received LMWH less than three months earlier (35 days) the platelet count fell dramatically two days after heparin administration, while in all other patients (including those who had been treated with heparin more than three months earlier) HIT did not occur before five days of LMWH administration (in 6 patients within the first week, and in additional 7 within the second week). Finally, out of the 320 patients who had a longer follow-up after LMWH discontinuation, none developed delayed-onset HIT (0%; 95% CI, 0 to 1.15%). Although the number of patients who had a long-term follow-up was too small to draw reliable conclusions, the rate of delayed-onset HIT in medical patients treated with LMWH may be as low as that occasionally observed in patients treated with UFH (13,14).

A number of methodological issues deserve attention. As we did not perform a baseline search for heparin-dependent antibodies, we cannot exclude that in a number of patients who subsequently developed HIT (especially in those who had previously been exposed to heparin) these antibodies were already present at time of patients recruitment. In particular, as we were not able to identify among the many patients who had a previous heparin exposure the ones who had been treated with UFH, we cannot exclude that in a number of HIT patients this complication developed as a result of antibodies produced by prior UFH exposition. In addition, as we did not systematically search for heparin-dependent antibodies in all patients during LMWH treatment, we cannot exclude that the formation of IgG occurred in a proportion of patients higher than that identified (15). All of these are important issues and need to be addressed in future investigations. However, the purpose of our investigation was to make an estimate of the risk of clinically relevant HIT
exhibited by those hospitalized and ambulatory medical patients who are currently treated with LMWH. This is an important information for clinicians, as every day millions people receive LMWH for prophylaxis or treatment of thromboembolic disorders. The rate of LMWH-associated HIT we observed is plausible and consistent with that found in other series of medical patients treated with UFH or LMWH (16). The validity of our approach is confirmed by the high prevalence of unexpected thromboembolic complications among patients labeled as affected by HIT, which fully compares with that observed in patients treated with UFH (1-5), but contrasts with that observed in the remaining patients of our cohort.

We believe that the results of our study are widely applicable, since a large number of consecutive patients with a broad spectrum of medical diseases requiring prophylactic or therapeutic administration of LMWH were included and prospectively followed until heparin discontinuation or later. Confounding factors were minimized by excluding patients suffering from diseases potentially responsible for non-immune thrombocytopenia. For the definition of HIT sensitive and specific criteria were adopted. The diagnosis of HIT was indeed accepted only in case of a platelet drop of at least 50% of pretreatment value, the absence of obvious explanations for thrombocytopenia, and the demonstration of heparin-dependent IgG antibodies obtained by using validated antigen and activation assays (17). Finally, all suspected thromboembolic events were objectively confirmed.

In conclusion, HIT and HIT-related thromboembolic complications are relatively common adverse effects of LMWH treatment in medical patients. They affect especially those patients who have been previously exposed to heparin. Our findings suggest that, at least in medical patients, both the incidence of HIT and the prevalence of thromboembolic complications are consistent with those expected in patients treated with UFH. Since the use of LMWH has largely replaced that of UFH in clinical practice, operators should be alerted and adopt in all patients candidate to
LMWH those precautions that have long been suggested for prevention and early
detection and treatment of immune thrombocytopenia in patients candidate to
standard heparin, including a close clinical and laboratory surveillance at least in the
first two weeks.
