ABSTRACT

Aplastic anemia, an unusual hematologic disease, is the paradigm of the human bone marrow failure syndromes. Almost universally fatal just a few decades ago, aplastic anemia can now be cured or ameliorated by stem cell transplant or immunosuppressive drug therapy. The pathophysiology is immune-mediated in most cases, with activated type 1 cytotoxic T cells implicated. The molecular basis of the aberrant immune response and deficiencies in hematopoietic cells is now being defined genetically; examples are telomere repair gene mutations in the target cells and dysregulated T cell activation pathways. Immunosuppression with antithymocyte globulins and cyclosporine are effective at restoring blood cell production in the majority of patients, but relapse and especially evolution of clonal hematologic diseases remain problematic. Allogeneic stem cell transplantation from histocompatible sibling donors is curative in the great majority of young patients with severe aplastic anemia; the major challenges are extending the benefits of transplant to patients who are older or who lack family donors. Recent results with alternative sources of stem cells and a variety of conditioning regimens to achieve their engraftment have been promising, with survival in small pediatric case series rivaling conventional transplant results.
More than 25 years have passed since our first, highly speculative review of aplastic anemia; in that fortunately obscure publication, pathophysiology was addressed tentatively and immunosuppressive therapies hardly at all. The article did reflect both the dismal prospects for patients with the severe form of marrow failure and the formidable practical difficulties of experimentation in a rare disorder in which the cells of interest had disappeared. Aplastic anemia was considered heterogenous in origin and virtually impossible to study systematically. At the bedside, the clinical emphasis was the identification of a putative causal factor—exposure to benzene or a culpable pharmaceutical—to allow classification in an otherwise doomed patient. As progenitor assays were developed, diverse factors could be held theoretically responsible failure to form colonies in tissue culture, ranging from quantitative and qualitative defects in stem cells and blocks in differentiation to a lack of stroma support or inadequate cytokine production, or the effects of a chemical poison.

In the intervening decades, our understanding of aplastic anemia has cohered around a unified immune mechanism of hematopoietic cell destruction, which was inferred from but also has informed effective immunosuppressive therapies for the disease (Fig. 1). Technical advances in cell biology, flow cytometry, molecular biology, and immunology have provided methods to measure numbers and function of very limited numbers of cells. As a result, we have a more unified and rational view of aplastic anemia’s pathophysiology; the disease is understood in its relation to other related marrow failure syndromes; and in many important respects an unusual blood syndrome can model more common autoimmune diseases of other organ systems (Fig. 2). Particularly satisfying is that aplastic anemia is now amenable to cure or amelioration in most patients, based both on high quality clinical trials and mechanistic insights from the experimental laboratory.

Our intention in this circumscribed review is to emphasize the most current aspects of aplastic anemia. As a complement, the reader is referred to monographs, textbook chapters, and other recent reviews1-6.

ETIOLOGIES

Clinical Associations. Since Ehrlich’s description of the first case of aplastic anemia in a pregnant woman, precipitating factors have been sought from the individual patient’s history. An enormous literature, dating from the beginning of the 20th century, described chemical- and drug-induced disease, stimulated by observations of the effects of benzene on blood counts, of dipyrone’s association with agranulocytosis, and a seeming epidemic of aplastic anemia after the introduction of chloramphenicol.

These associations are worth reassessment in the context of the immune hypothesis of marrow failure. Pregnancy appears a real association, as deduced more from the documented improvement of blood counts with its termination than from formal epidemiologic study7. The unusual syndrome of eosinophilic fasciitis also is strongly linked to aplastic anemia. Five to ten percent of cases of aplastic anemia follow an episode of seronegative hepatitis, in which immune activation is inferred from the pattern of T cell activation, cytokine production, and HLA association8. Despite intensive efforts, including sophisticated molecular and immunologic approaches and animal inoculations, an infectious agent has not been identified. Benzene, or more correctly its metabolites, is a marrow toxin in animals and man, but in the West benzene exposure as an etiology of aplastic anemia is now rare. Ancient case reports and series leave
doubt as to whether marrow failure in benzene workers was not often myelodysplasia rather than aplastic anemia. Additionally, benzene also has effects on immune function.

Of greatest practical import is the relationship of medical drug use to aplastic anemia—unpredictable marrow failure in this setting is devastating to the patient and physician and has serious legal ramifications in for pharmaceutical drug development. The study of idiosyncratic drug reactions, by definition extremely rare, is difficult. That genetic differences in drug metabolism, especially in detoxification of reactive intermediate compounds, underlie susceptibility is best supported by one study of a single individual exposed to carbamazepine, published over 20 years ago. Overrepresentation of deletions in the drug metabolizing glutathione-S-transferase genes (GSTM1, GSTT1, which would increase concentrations of toxic drug intermediates) have been observed in some series. Astonishingly, no satisfactory mechanism has been developed for the most notorious pharmaceutical, chloramphenicol, or for other heavily inculpated agents like penicillamine or gold. Many drugs on “black lists” also more commonly cause mild marrow suppression, and possibly regular but only modest destruction of marrow cells is a prerequisite for a much more infrequent immune response to an exposed neoantigen. A parallel mechanism is supported by the clinical observation of little difference between patients with idiopathic aplastic anemia and those with an assumed drug etiology, in demographics, response to therapy, or survival. In contrast, very few chemotherapeutic agents, despite being designed as cell poisons and administered in milligram or gram quantities, directly result in irreversible marrow destruction without obvious effects on other organs. Claims of permanent aplastic anemia after idiosyncratic exposure to minuscule quantities of chloramphenicol, for example (as in ophthalmic solutions) likely reflect observation and reporting biases than a mechanism of extreme sensitivity to a hidden metabolite.

Epidemiology. Two more reliable approaches to identifying etiology are epidemiology and laboratory identification of antigens. Unfortunately, neither has yielded conclusive results. Two large, controlled population-based studies have been conducted, the International Aplastic Anemia and Agranulocytosis Study in Europe and Israel in the 1980s and the recently completed Thai NHLBI Aplastic Anemia Study in Bangkok and a northeast rural region. The incidence of aplastic anemia in the West is 2/million and about 2-3-fold higher in Asia. Benzene and pesticides, while significantly associated, accounted for only a small number of cases in both studies, and medical drugs have a negligible role in Asia. In rural Thailand, exposure to nonbottled water, as well as to certain animals (ducks and geese), to animal fertilizer, and also to pesticides suggested an infectious etiology.

Autoantigens. A few putative antigens have been teased from screening antibodies in patients’ sera against a peptide library (by expression of genes in fetal liver or leukemic cell lines). Kinectin, a widely expressed protein, bound to antibodies from about 40% of aplastic patients. Another antigen that bound to antibodies, in a smaller minority of marrow failure patients, was diazepam-binding related protein-1, an enzyme essential in the oxidation of unsaturated fatty acids and broadly distributed in tissues. The relevance of these autoantibodies to a cellular pathophysiology of aplastic anemia is unclear. For kinectin, reactive cytotoxic T cells could be generated in vitro and inhibited human hematopoietic colony formation, but anti-kinectin T cells were not found in patients. For diazepam-binding related protein-1, a putative T cell epitope derived from this protein could stimulate cytotoxic T cells obtained from one patient, and T cell precursors with peptide-binding activity were present in two cases.
PATHOPHYSIOLOGY

In most cases, aplastic anemia is an immune-mediated disease. Cellular and molecular pathways have been mapped in some detail for both effector (T lymphocyte) and target (hematopoietic stem and progenitor) cells (Fig. 3). Exposure to specific environmental precipitants, diverse host genetic risk factors, and individual differences in the characteristics of the immune response likely account for the disease’s infrequency, variations in its clinical behavior, and patterns of responsiveness to treatment.

Immune-mediated T cell destruction of marrow.

An immune mechanism was inferred decades ago from the recovery of hematopoiesis in patients who failed to engraft after stem cell transplant, when renewal of autologous blood cell production was credited to the conditioning regimen. Also suggestive was that the majority of syngeneic transplants in which bone marrow was infused without conditioning failed. The responsiveness of aplastic anemia to immunosuppressive therapies remains the best evidence of an underlying immune pathophysiology: the majority of patients show hematologic improvement after only transient T cell depletion by antithymocyte globulins (ATG); relapse also usually responds to ATG; and dependence of adequate blood counts on administration of very low doses of cyclosporine is not infrequent. As immunosuppression has intensified, from early attempts with corticosteroids to aggressive strategies like high dose cyclophosphamide, and the proportion of responders has risen, the willingness to ascribe an immunological mechanism also increased. Indeed, little distinguishes responders to immunological therapy from refractory patients (other than age, as children show higher rates of recovery and survival). A nonimmune pathophysiology has been inferred from a failure to respond to immunosuppression, but refractoriness to therapy is also consistent with very severe stem cell depletion, a "spent" immune response, or immunological mechanisms not susceptible to current therapies.

In early laboratory experiments, removal of lymphocytes from aplastic bone marrows improved colony numbers in tissue culture, and their addition to normal marrow inhibited hematopoiesis in vitro (reviewed in). The effector cells were identified by immunophenotyping as activated cytotoxic T cells expressing Th1 cytokines, especially γ-interferon. CD8 cells containing intracellular interferon may now be measured directly in the circulation, and oligoclonal expansion of CD8+ CD28- cells, defined by i) flow cytometric analysis for T cell receptor (TCR) Vβ subfamilies; ii) spectratyping to detect skewing of CDR3 length; and iii) sequencing of the CDR3 region to establish a molecular clonotype. In general, patients at presentation demonstrate oligoclonal expansions of a few Vβ subfamilies, which diminish or disappear with successful therapy; original clones reemerge with relapse, sometimes accompanied by new clones, consistent with spreading of the immune response. Very occasionally, a large clone persists in remission, perhaps evidence of T cell tolerance.

The impact of T cell attack on marrow can be modeled in vitro and in vivo. γ-interferon (and tumor necrosis factor-α) in increasing doses reduce numbers of human hematopoietic progenitors assayed in vitro; the cytokines efficiently induce apoptosis in CD34 target cells, at least partially through the Fas-dependent pathway of cell death. In long-term culture of human bone marrow, in which stromal cells were engineered to constitutively express γ-interferon, the output of long-term culture-initiating cells (LTCI-IC) was markedly diminished, despite low concentrations of the cytokine in the media, consistent with local amplification of toxicity in the marrow milieu. Immune-mediated marrow failure has been modeled in the mouse: infusion of
parental lymph nodes cells into F1 hybrid donors caused pancytopenia, profound marrow aplasia, and death. Not only a murine version of ATG and cyclosporine but also monoclonal antibodies to γ-interferon and tumor necrosis factor abrogated hematologic disease, rescuing animals. A powerful “innocent bystander” effect, in which activated cytotoxic T cells kill genetically identical targets, was present in secondary transplant experiments. In a minor histocompatibility antigen-discordant model, marrow destruction resulted from activity of an expanded H60 antigen-specific T cell clone.

Why T cells are activated in aplastic anemia is unclear. HLA-DR2 is over-represented among patients, suggesting a role for antigen recognition, and its presence is predictive of a better response to cyclosporine. Polymorphisms in cytokine genes, associated with an increased immune response, also are more prevalent: a nucleotide polymorphism in the tumor necrosis factor-α (TNF2) promoter at -308, homozygosity for a variable number of dinucleotide repeats in the gene encoding γ-interferon, and polymorphisms in the interleukin 6 gene. Constitutive expression of Tbet, a transcriptional regulator that is critical to Th1 polarization, occurs in a majority of aplastic anemia patients. Mutations in PRF1, the gene for perforin, are responsible for some cases of familial hemophagocytosis; mutations in SAP, a gene encoding for a small modulator protein that inhibits γ-interferon production, underlie X-linked lymphoproliferation, a fatal illness associated with an aberrant immune response to herpesviruses and aplastic anemia. Perforin is over-expressed in aplastic marrow. We have detected homozygous mutations in PRF1 in an adult with severe aplasia and hemophagocytosis of the marrow, and SAP protein levels are markedly diminished in a majority of acquired aplastic anemia cases (Solomou E, unpublished data). These alterations in nucleotide sequence and in gene regulation suggest a genetic basis for aberrant T cell activation in bone marrow failure. Genome wide transcriptional analysis of T cells from aplastic anemia patients has implicated components of innate immunity in aplastic anemia, including Toll-like receptors and natural killer cells, for which there is some preliminary experimental support.

Hematopoiesis. Immune attack leads to marrow failure. “Anhematopoiēsis” was inferred from the empty appearance of the marrow at autopsy by the earliest observers of the disease. The pallor of the modern biopsy core or empty spicules of an aspirate, few or no CD34 cells on flow cytometry, and minimal numbers of colonies derived from committed progenitors in semisolid media all reflect the severe reduction in hematopoietic cells that defines the disease. Stem cell “surrogate”—really correlative—assays, LTC-IC or cobblestone forming cells, which measure a primitive infrequent and quiescent multipotential progenitor cell, also show marked deficiency, and from the product of the low percentage of marrow cellularity and the scant numbers of LTC-IC per mononuclear cell, suggest that only a few percentage of residual early hematopoietic cells remain in severely affected patients at presentation. Qualitative features of these few cells, as measured, for example, by poor colony formation per CD34 cell or inadequate response to hematopoietic growth factors, are harder to interpret, although recent genetic studies have suggested explanatory mechanisms (see below). The reduced number and function of the marrow is secondary to cell destruction, and apoptosis is prevalent among the few remaining elements. Microarray of the scant CD34 cells from marrow failure patients revealed a transcriptome in which genes involved in apoptosis, cell death, and immune regulation were upregulated; this transcriptional signature was reproduced in normal CD34 cells exposed to γ-interferon.
One peculiar feature of white blood cells in aplastic anemia is short telomeres. Telomere shortening was initially most easily blamed on stem cell exhaustion. However, the discovery, first by linkage analysis in large pedigrees, that the X-linked form of dyskeratosis congenita was due to mutations in *DKC1* and subsequently purposeful identification of mutations in *TERC* in some autosomal dominant patients with this constitutional marrow failure syndrome indicated a genetic basis for telomere deficiency. Central to the repair machinery is an RNA template, encoded by *TERC*, on which telomerase, a reverse transcriptase encoded by *TERT*, elongates the nucleotide repeat structure; other proteins, including the *DKC1* gene product dyskerin, are associated with the telomere repair complex. Systematic surveys of DNA disclosed first *TERC* and later *TERT* mutations in some patients with apparently acquired aplastic anemia, including older adults. Family members who share the mutation, despite normal or near normal blood counts, have hypocellular marrows, reduced CD34 cell counts and poor hematopoietic colony formation, increased hematopoietic growth factor levels, and of course short telomeres; however, their clinical presentation is much later than in typical dyskeratosis congenita, and they lack typical physical anomalies. Chromosomes are also protected by several proteins that bind directly to telomeres, and polymorphisms in their genes (*TERF1*, *TERF2*) are also more or less prevalent in aplastic anemia compared to healthy controls. A few of our patients also have heterozygous mutations in the Shwachman-Bodian-Diamond syndrome (*SBDS*) gene. Almost all children with this form of constitutional aplastic anemia are compound heterozygotes for mutations in *SBDS*, and their white cells have extremely short telomeres; however, the *SBDS* gene product has not been directly linked to the telomere repair complex or to telomere binding. A parsimonious inference from all these data is that inherited mutations in genes that repair or protect telomeres are genetic risk factors in acquired aplastic anemia, probably because they confer a quantitatively reduced hematopoietic stem cell compartment that may also be qualitatively inadequate to sustain immune mediated damage.

Telomeres are short in one third to ½ of aplastic anemia patients but mutations have only been identified in less than 10% of cases. The most interesting explanation is involvement of other genes, including for other members of the large repair complex, telomere binding proteins, still obscure components of the alternative repair system, and some DNA helicases. Alternatively, telomere shortening may be secondary to stem cell replication.

**Clonal Evolution**

Clinically, aplastic anemia may coexist or appear to evolve to other hematologic diseases which are characterized by proliferation of distinctive cell clones, as in paroxysmal nocturnal hemoglobinuria (PNH) or myelodysplasia (MDS; Fig. 2). The mechanisms linking immune-mediated and premalignant pathophysiologies are not elucidated in marrow failure or in parallel circumstances (chronic hepatitis and hepatocellular carcinoma, ulcerative colitis and colon cancer, and many others). The presence of tiny clones at the time of diagnosis of aplastic anemia, detected using extremely sensitive assays—phenotypic (flow cytometry for PNH) or cytogenetic (fluorescent in situ hybridization for MDS)—also creates problem of disease classification and patient diagnosis.

**PNH.** Fifty percent or more of patients at presentation with pancytopenia have expanded populations of PNH cells, easily detected by flow cytometry due to the absence of glycosylphosphatidylinositol-linked membrane proteins, the result of somatic *PIG-A* gene mutations. Most clones are small and do not lead to clinical manifestations of hemolysis or
thrombosis but classic PNH can be dominated by marrow failure (the “aplastic anemia/PNH syndrome”) and all PNH patients show evidence of underlying hematopoietic deficiency. The global absence of large number of cell surface proteins in PNH has been hypothesized to allow “escape” and survival of a pre-existing mutant clone. Association of an expanded PNH clone with HLA-DR2 and with autoantibodies, and as a predictor of responsiveness to immunosuppressive therapies all suggest that the escape is from immune attack. However, there is little concrete experimental evidence of reproducible differences in either differential immune responsiveness or susceptibility of PNH clones compared to phenotypically normal target cell populations. In contrast to cells of normal phenotype, the marrow PNH clone retains its proliferative capacity in tissue culture and does not over-express Fas; comparison by microarray shows that residual cells of normal phenotype in the PNH bone marrow upregulate the same apoptosis and cell death genes as do CD34 cells in aplastic marrow, while the PIG-A-clone appears transcriptionally similar to CD34 cells from normal donors. Despite a few provocative studies, no satisfying mechanism to explain clonal escape has convincing empiric support (see for review).

MDS. Stereotypical patterns of aneuploidy develop in a minority of patients over time: monosomy 7 or trisomy 8 are most characteristic. Trisomy 8 is MDS with many immune abnormalities that resemble aplastic anemia. Patients respond to immunosuppressive therapies, and oligoclonal T cell expansions are usually present. T cell oligoclones appear to recognize the aneuploid cells, and specifically WT1 antigen that they express at high levels, but the target cells are not killed due to upregulation of anti-apoptosis genes, including c-myc, survivin, and CDK1. For trisomy 8, abnormal cells targeted by the immune system appear to be selected for their capacity to survive cytotoxic lymphocyte attack.

Monosomy 7 is also a frequent cytogenetic abnormality in aplastic anemia but has a poorer prognosis, patients usually succumbing to refractory cytopenias or evolving to acute leukemia. Emergence of monosomy 7 has been linked to exogenous use of G-CSF in aplastic anemia, as occurs in treated severe congenital neutropenia. Laboratory studies of marrow from aplastic anemia and myelodysplasia patients suggest that monosomy 7 clones expand in an abnormal cytokine milieu: high G-CSF concentrations lead to selection of cells which bear a short isoform of the G-CSF receptor that signals proliferation but not differentiation.

TREATMENT

Immunosuppression

Antithymocyte globulin (ATG) and cyclosporine (combined or intensive immunosuppression). For aplastic anemia that is severe, as defined by peripheral blood counts, definitive therapies are immunosuppression or stem cell transplantation; immunosuppressive therapies are most widely employed because of lack of histocompatible sibling donors, patient age, and the immediate cost of transplant. Even in responding patients, blood counts often remain below normal but adequate to avoid transfusion and to prevent infection. Most specialists employ an ATG-based regimen in combination with cyclosporine, based on the outcomes of relatively large studies performed in the 1990s (Table 1). The larger experience is with ATG produced in horses, although a rabbit ATG, recently approved for use in the United States, is more potent by weight and in the treatment of graft rejection after solid organ transplants (a current NIH trial is directly comparing these two ATGs as first therapy in severe aplastic anemia). ATG is cytolytic: lymphocyte numbers consistently decline during the first
few days of infusion and then return to pre-treatment levels in a week or two. ATGs are produced by immunizing animals against human thymocytes, not lymphocytes, and the mix of antibody specificities plus direct experimentation suggest that ATG may be immunomodulatory as well as lymphocytotoxic, perhaps producing a state of tolerance by preferential depletion of activated T cells. The toxicity of ATG is allergic, related to administration of a heterologous protein, and there is little added infection risk beyond the neutropenia intrinsic to the disease. ATG doses and regimens are empiric and traditional. By administration of a larger dose over fewer days, immune complex formation and consequent serum sickness, are minimized, as patients usually do not produce their own antibodies to the foreign protein until a week or ten days after exposure.

Cyclosporine’s selective effect on T cell function is due to direct inhibition on the expression of nuclear regulatory proteins, resulting in reduced T cell proliferation and activation. While severe aplastic anemia can respond to cyclosporine alone, it is less effective than either ATG alone or ATG plus cyclosporine. As with ATG, doses and length of treatment have not been formally established. Cyclosporine has many side effects, but most are manageable by dose reduction; permanent kidney damage is unusual with monitoring (to maintain blood levels at nadir of about 200 ng/ml). Maintenance of blood counts may be achieved with very low doses of cyclosporine, such that drug levels in blood are undetectable and toxicity minimal, even with years of treatment.

Outcomes of combined immunosuppressive therapy. Reported hematologic response rates vary, at least in part due to lack of consensus on parameters (transfusion-independence, absolute or relative improvement in blood counts) and defined landmarks. In our experience, improvement of blood counts so that the criteria for severity are no longer met highly correlates with termination of transfusions, freedom from neutropenic infection, and better survival. By this standard, about 60% of patients are responders at 3 or 6 months post-initiation of horse ATG. Comparable figures for hematologic response rates have come from Europe and Japan. Survivors have a much better survival prospects than do nonresponders. Long-term prognosis is predicted by the robustness of the early blood count response (defined as either platelets or reticulocytes >50,000/uL 3 months after treatment): about 50% of patients who are treated with horse ATG have a robust response and almost all of them will survive long-term. Outcomes of immunosuppressive therapy are related to patient age: 5 year survival of >90% of children has been reported in recent German, Japanese, and Chinese trials, compared to about 50% survival for adults >60 years old in the collective European experience.

Relapse, defined conservatively as a requirement for additional immunosuppression and not necessarily recurrent pancytopenia, is not uncommon, occurring in 30-40% of responding patients. Relapse defined by renewed need for transfusion was estimated at 12% of European patients at 3 years, but prolonged cyclosporine-dependency among all patients was common. Reinstitution of cyclosporine usually reverses declining blood counts, but when required, a second round of horse or rabbit ATG is usually effective. In our experience, relapse does not confer a poor prognosis, but it is obviously inconvenient and may not always be remediable. Molecular analysis of the T cell response in aplastic anemia, discussed above, suggests that the major reason for relapse is incomplete eradication of pathogenic clones by ATG.

More serious than relapse is evolution of aplastic anemia to another clonal hematologic disease, PNH, myelodysplasia, and leukemia. Small PNH clones present at diagnosis usually remain stable over time but may expand sufficiently to produce symptomatic hemolysis.
myelodysplasia and leukemia, the cumulative long-term rate of clonal evolution is about 15%\textsuperscript{70,78}; evolution is not inevitable in aplastic anemia, and some cytogenetic abnormalities may be transient or, as with trisomy 8, responsive to immunosuppressive treatments. As discussed above, emergence of monosomy 7 may be favored in severely neutropenic patients who require chronic G-CSF therapy\textsuperscript{66}.

**Improving on ATG and cyclosporine.** **Growth factors.** Historically, intensification of immunosuppression has increased response rates. However, attempts to improve on ATG plus cyclosporine have been frustratingly disappointing. Megadoses of methylprednisolone only added toxicities. Small pilots of GM-CSF\textsuperscript{79} and much larger, randomized studies of G-CSF\textsuperscript{72,80} as routine additions to ATG and cyclosporine have been negative to date, improved neutrophil counts not translating to a higher rate of recovery or even less infection. A very large ongoing European study of G-CSF should definitively answer efficacy and safety concerns.

**Other immunosuppressive drugs.** As the addition of cyclosporine clearly improved outcomes compared to the use of ATG alone, other immunosuppressive drugs might be predicted, based on their mode of action, animal studies, and experience in other human diseases and with organ transplant, to be effective. Mycophenolate mofetil is a tolerizing agent, as it selectively depletes for activated cells by inhibition of inosine monophosphate dehydrogenase, a critical enzyme of the purine salvage pathway, therefore blocking activated lymphocyte proliferation. Nonetheless, its addition to ATG and cyclosporine in an NIH trial of 104 patients did not change hematologic response (about 62%), relapse (37%), or evolution rates; at best, there was a modest sparing of cyclosporine usage\textsuperscript{81}. The 4-year survival rate for all treated patients was 80%–almost certainly due to better supportive care rather than any new drug effect. Sirolimus, which blocks the serine-threonine kinase “mammalian target of rapamycin” is synergistic with cyclosporine in tissue culture and in clinical transplant. Again, when tested in a randomized protocol in combination with ATG and cyclosporine in aplastic anemia, results were not superior to these agents only (our unpublished data).

**Cyclophosphamide.** As with ATG, recovery of blood counts can occur after a failed bone marrow transplant preceded by conditioning with cyclophosphamide. High dose cyclophosphamide was used intermittently by investigators at Johns Hopkins in the 1980s during periods in which ATG apparently was not available to them; in their most recent update, of 38 previously untreated patients, the response rate was 74% and survival estimated at 86%\textsuperscript{82,83}. In contrast, an NIH randomized study was halted early due to the development of fungal infections and a much higher death rate in the cyclophosphamide arm\textsuperscript{84}, and both relapse and cytogenetic evolution were observed\textsuperscript{85}. The major toxicity of high dose cyclophosphamide, prolonged neutropenia with concomitant susceptibility to infection, is now addressed by the Baltimore investigators by routine antimicrobial prophylaxis and prolonged G-CSF administration. Cyclophosphamide therapy does not eradicate PNH clones, and relapses now have been observed in Baltimore\textsuperscript{83}. In the absence of another randomized trial, comparison of data from a small, single center pilot with historical and more general results is problematic; it is especially difficult to exclude biased patient selection, explicit (such as exclusion of those unlikely to respond or with a generally poor prognosis or older patients) and implicit (inability to treat uninsured individuals or foreign citizens).

**Management of refractory aplastic anemia.** There is no established algorithm for the management of patients who have failed to respond to ATG\textsuperscript{67}. Transplantation from an alternative donor is offered by many centers to children who have failed a single course of
immunosuppression and to adults after two rounds of ATG therapy (see below). Response rates to second ATG have ranged from 22% to 64%76. In an Italian study of rabbit ATG as second therapy, 23/30 (77%) improved86; in the NIH experience, the proportion responding was closer to 30%81. Cyclophosphamide also has been administered in this setting, with a response rate of about 50% reported82. A third course of immunosuppression may only benefit patients who showed some response to a previous treatment87. Response to retreatment correlates to a better survival compared to refractory patients81. The improved survival of patients who are refractory to immunosuppression, due to better supportive care, complicates the decision to undertake high risk transplantation (see below). We have tested Campath, a humanized monoclonal antibody specific for CD52, an antigen present on all lymphocytes; Campath induces profound immunosuppression by lymphocytotoxicity and has been effective in lymphoproliferative diseases, graft-versus-host disease and in autoimmune disorders. To date, 4/8 patients who were refractory to treatment with horse ATG have responded to Campath, and toxicity has been modest (our unpublished data); we are now testing Campath in a randomized comparison with both horse and rabbit ATG in severe aplastic anemia at presentation.

Treatment of moderate pancytopenia. Clinically, the course of moderate aplastic anemia is variable: some patients progress to severe disease, others remain stable and may not require intervention; regular transfusions may not be required88. Very few clinical trials have specifically addressed moderate disease. Immunosuppression can reverse moderate pancytopenia and alleviate transfusion requirements; ATG and cyclosporine are more effective in combination68 but in practice are often employed sequentially. Daclizumab, a humanized monoclonal antibody to the interleukin-2 receptor, improved blood counts and relieved transfusion requirements in 6 of 16 evaluable patients; the outpatient regimen had little toxicity89. When there is residual hematopoietic function, androgens may be effective (although male hormones have failed most rigorous trials in severe aplastic anemia). Some moderate aplastic anemia likely results from telomere gene mutations and stem cell exhaustion. In vitro, androgens increase telomerase activity in human lymphocytes and CD34 cells, acting through the estradiol receptor90, and this activity may provide a mechanism of action for their effects on marrow function.

Hematopoietic Stem Cell Transplantation

Allogeneic HLA-matched sibling donor transplant. Hematopoietic and immune system cells are replaced by stem cell transplant; conditioning with cyclophosphamide is not myeloablative but is sufficiently immunosuppressive to prevent and to eliminate residual host marrow by a graft-versus-marrow effect.

Allogeneic transplant from a matched sibling donor cures the great majority of patients (Table 2): the most recent cohort reported to the IBMTR showed 77% 5-year survival91, and in children, and patients entering transplant who are minimally transfused, survival of 80-90% may be routinely achieved. Graft rejection, a historic problem in the application of transplant to aplastic anemia (most dramatically manifest in rejection of unprepared syngeneic stem cells), is now not frequent in patients transplanted early and with a modest transfusion burden, likely a benefit of less immunogenic blood products (leucocyte-depleted erythrocytes, for example) from fewer donors (platelets collected by cytopheresis). Conditioning regimens that do not include irradiation now regularly achieve engraftment and avoid many of irradiation's long-term complications, especially late cancers. In a recent series of 81 patients who were prepared by
cyclophosphamide plus ATG, sustained engraftment was achieved by 96%, and three of the four patients who rejected were successfully retransplanted; 88% of patients survived long-term. The combination of cyclophosphamide plus fludarabine, with or without ATG have achieved high rates of graft acceptance and survival even in heavily transfused patients who were transplanted with mobilized peripheral blood stem cells, months after proving refractory to immunosuppressive drugs.

Graft-versus-host disease remains a serious problem for older patients, even with routine cyclosporine prophylaxis. In the IBMTR, rates of severe GVHD doubled in adults compared to children (15-20% for recipients <20 years old to 40-45% for >21 years of age). In Seattle, chronic graft-versus-host disease developed in 41% of patients who had survived more than two years after transplant, tripling the risk of death and often requiring years of immunosuppressive therapy. Even with resolution, chronic GVHD remains a risk factor for late complications like growth and endocrine system effects, pulmonary disease, cataracts, neurologic dysfunction, and secondary malignancy. Addition of ATG and more recently its substitution by Campath may reduce the frequency and severity of acute GVHD, a predictor of chronic GVHD (although the latter has been associated with increased rejection rate).

**Matched unrelated donor transplant.** A matched sibling donor is available in only 20-30% of cases. As the outcome in aplastic patients who have failed a single round of ATG has been poor, alternative sources of hematopoietic stem cells have been sought, usually from now very large donor registries (Table 3). Outcomes of 318 alternative donor transplants performed from 1988 to 1998 recently have been summarized for the European registry: for matched unrelated donors, the rejection rate was 15% and for grade II-IV GVHD, 48%, and 5-year survival was estimated at 39%. From diverse registries data (collected through EBMT, IBMTR, and the National Marrow Donor Program), the mortality rate is about twice that observed in matched sibling transplants; even with predominantly younger patients as recipients, age is probably the most powerful influence on survival, but also important are the closeness of the class I HLA match and the length of time from diagnosis. A retrospective analysis from the Japan Marrow Donor Program suggested that patients with the most favorable characteristics and conditioned with a minimal dose of radiation might anticipate survival comparable to matched sibling transplants.

Prospective trials have enrolled fewer patients but have better results (perhaps due to superior protocols, but both careful patient selection and publication bias are likely important). In contrast to allogeneic sibling transplants, transplants from unrelated donors still require irradiation to ensure engraftment, due both to source of the donor cells and the transfusion status of the recipient. In a recent multi-center study, 62 patients with severe aplastic anemia who were refractory to immunosuppressive therapy underwent matched unrelated stem cell transplant following conditioning with cyclophosphamide, ATG, and total body irradiation; graft failure occurred in 2%, acute grade II-IV GVHD was observed in 70%, chronic GVHD in 52%, and overall survival was 61%; 25 patients who lacked an HLA-identical donor received an HLA-nonidentical stem cell graft: 88% showed sustained engraftment and overall survival was 44%. The interval from diagnosis to transplant in this study did not impact survival.

A European protocol substituted irradiation with fludarabine for unrelated and mismatched family donors: 73% were estimated to survive 2 years; while GVHD rates were relatively low, perhaps due to absence of radiation damage, graft rejection occurred in about a third of the older children and younger adults. Children’s Hospital of Milwaukee pioneered a rigorous
conditioning regimen of cytosine arabinoside, cyclophosphamide, and total body irradiation, which produced long-term survival of about 50% with very little GVHD\textsuperscript{103}. Other single institution protocols have used a diversity of strategies to improve graft acceptance and reduce GVHD–T cell depletion, CD34 cell purification, Campath, chemotherapy and monoclonal antibodies in combination; while almost exclusively enrolling small numbers of children and still preliminary, survival and morbidity may rival results of conventional sibling transplants. In current practice, unrelated transplant is offered for children who have failed a single course of immunosuppression and to adults who are refractory to multiple courses of ATG and alternative therapies like androgens. Studies with longer follow-up of larger numbers are crucial to establish the optimal conditioning regimen and to define which patients will benefit and especially how early unrelated transplant should be performed.

**Other stem cell sources.** HLA mismatching is better tolerated for umbilical cord transplants, making them in theory widely applicable. Published data for this procedure in marrow failure is limited, and almost all recipients have been small children, due to the small numbers of stem cell numbers contained in a single cord blood sample. In a report from the National Marrow Donor Program, engraftment occurred in less than half of 19 recipients, and almost all the patients died from transplant-related causes or survived due to autologous reconstitution or a second transplant\textsuperscript{104}. Surprisingly, 5 of 6 Chinese adult aplastic anemia patients successfully engrafted, and 4 survived\textsuperscript{105}. Advocates of this approach are employing pooled donations to increase stem cell numbers.

Family members are almost always available to the patient as a stem cell source, but survival after haploidentical transplantation has been poor. More recently, engraftment was achieved in three children using the St. Jude protocol, but one ultimately rejected and mixed chimerism in the others required further immunosuppression and donor lymphocyte infusions\textsuperscript{106}.

**CONCLUSIONS AND PROSPECTS**

The treatment of severe aplastic anemia, whether by allogeneic stem cell transplant or immunosuppression, has improved dramatically over the last 25 years, and long-term survival of more than 75\% of patients can be anticipated with either therapy\textsuperscript{107}. For transplant, the immediate challenge is the extension of stem cell replacement to all patients, regardless of age, with a histocompatible sibling, and to others who lack a family donor using alternative stem cell sources. Ability to achieve engraftment under these difficult circumstances may require conditioning regimens in which complications, particularly second malignancies, may not be apparent for many years. More optimistically, donor selection based on high resolution histocompatibility typing may improve outcomes. The success of umbilical cord blood transplants, with their low risk of GVHD, may be enhanced by larger pools and histocompatibility matching. For immunosuppression, many new drugs and biologics have yet to be tested in aplastic anemia. Again, the costs of intensification need to be balanced against the benefits of higher hematologic response rates and lower rates of relapse and evolution. Repeated courses of immunosuppression offer the possibility of blood count restitution to 75->90\% of patients, based on the range of published hematologic recovery rates with initial horse ATG followed by rabbit ATG, Campath, or cyclophosphamide. If residual stem cell numbers are limiting, ex vivo expansion of hematopoiesis may be possible, as for example using Hox box proteins. Quantitative and practical measurements of oligoclonal T cell activity and of hematopoietic stem cell number and function would allow laboratory testing to guide treatment.
decisions. Ultimately, definition of genetic risk factors, affecting hematopoietic cell function and the immune response, will clarify how agents in the environment initiate and perpetuate the marrow destruction of aplastic anemia.
ACKNOWLEDGMENTS

We are thankful to colleagues from the Hematology Branch, Drs. A. John Barrett, Cynthia Dunbar, Richard Childs, and Elaine Sloand, and in Europe, Professors Judith Marsh, Gérard Socié, and André Tichelli for their careful reading of the manuscript and helpful criticisms.

Only studies of >20 enrolled patients are tabulated. Responses to immunosuppressive therapy are usually partial; blood counts may not become normal but transfusions are no longer required and the neutrophil count is adequate to prevent infection. Relapse is usually responsive to further immunosuppressive therapies. Clonal evolution is to dysplastic bone marrow changes and/or cytogenetic abnormalities. For details, see accompanying text.

*With androgens and +/- G-CSF.

**With mycophenolate mofetil.

Figure Legends

Figure 1. Pathophysiology of acquired aplastic anemia. The figure stresses the crucial and related roles of the hematopoietic stem cell compartment as a target for the immune response. An inciting event, such as a virus or medical drug, provokes an aberrant immune response, triggering oligoclonal expansion of cytotoxic T cells which destroy hematopoietic stem cells (left panel, Onset). Bone marrow transplantation or immunsuppressive therapy lead to complete response (CR) or partial response (PR) by eradicating or suppressing pathogenic T cell clones (middle panel, Recovery). Relapse occurs with recurrence of the immune response, and the immunologically stressed and depleted stem cell compartment also allows selection of abnormal hematopoietic clones which manifest as paroxysmal nocturnal hemoglobinuria, myelodysplasia (MDS), and occasionally acute myelogenous leukemia (AML).

Figure 2. Venn diagram of the clinical and pathophysiologic relationships among the bone marrow failure syndromes, leukemia, and autoimmune diseases. Overlapping circles indicate difficulties in diagnostic discrimination and shared underlying mechanisms.

Figure 3. Immune destruction of hematopoiesis. Antigens are presented to T lymphocytes by antigen presenting cells (APC), which trigger T cells to activate and proliferate. T-bet, a transcription factor, binds to the interferon- (INF-) promoter region and induces gene expression. SAP binds to Fyn and modulates SLAM activity on IFN- expression, diminishing gene transcription. Patients with aplastic anemia show constitutive T-bet expression and low SAP levels. IFN- and TNF- up-regulate other T cell's cellular receptors and also the Fas receptor. Increased production of interleukin-2 leads to polyclonal expansion of T cells. Activation of Fas receptor by the Fas ligand leads to apoptosis of target cells. Some effects of IFN- are mediated through interferon regulatory factor 1 (IRF-1), which inhibits the transcription of cellular genes and entry into the cell cycle. IFN- is a potent inducer of many cellular genes, including inducible nitric oxide synthase (NOS), and production of the toxic gas nitric oxide (NO) may further diffuse toxic effects. These events ultimately lead to reduced cell cycling and cell death by apoptosis.
