Running title: MD-2 is an opsonin
ABSTRACT

Both Toll-like receptor 4 (TLR4) and MD-2 deficient mice succumb to otherwise non-fatal Gram negative bacteria inocula, demonstrating the pivotal role played by these proteins in anti-bacterial defense in mammals. MD-2 is a soluble endogenous ligand for TLR4 and a receptor for lipopolysaccharide (LPS). LPS-bound MD-2 transmits an activating signal onto TLR4. In this report we show that both recombinant and endogenous soluble MD-2 bind tightly to the surface of live Gram-negative bacteria. As a consequence, MD-2 enhances cellular activation, bacterial internalization and intracellular killing, all in a TLR4 dependent manner. The enhanced internalization of MD-2 coated bacteria was not observed in macrophages expressing Lps<sup>d</sup>, a signaling incompetent mutant form of TLR4, suggesting that the enhanced phagocytosis observed is dependent on signal transduction. The data confirms the notion that soluble MD-2 is a genuine opsonin which enhances pro-inflammatory opsonophagocytosis by bridging live Gram-negative bacteria to the LPS transducing complex. The presented results extend our understanding of the role of the TLR4/MD-2 signaling axis in bacterial recognition by phagocytes.
INTRODUCTION

Recognition of bacterial lipopolysaccharides (LPS) by mammalian cells depends upon the presence of both Toll-like receptor 4 (TLR4, CD284) and MD-2 (Ly96)\textsuperscript{1-3}. TLR4 is a 110 kDa type I integral membrane glycoprotein characterized by the presence of multiple leucine-rich repeats (LRR) on its ectodomain and a signalling Toll-Interleukin-1 receptor Resistance (TIR) domain on the cytoplasmic side. MD-2 is a 25-30 kDa secreted glycoprotein which belongs to the MD-2-Lipid binding (ML) family of single domain lipid-binding secreted proteins\textsuperscript{4}. MD-2 binds non covalently to the extracellular domain of TLR4\textsuperscript{5} and is tethered on the surface of cells expressing TLR4\textsuperscript{6}. The apparent $k_d$ of this interaction, as determined for human MD-2/TLR4, is approximately 12 nM\textsuperscript{7}. In addition to binding to TLR4, MD-2 binds specifically to the lipid portion of LPS (lipid A). Lipid A from enterobacteriaceae is a collection of phosphorylated glucosamine-based saccharolipids with up to 7 acyl moieties. This highly hydrophobic structure anchors LPS to the outer leaflet of the cell wall of Gram-negative bacteria\textsuperscript{8} and is the epitome of an innate immune stimulator. The crystal structures of MD-2 bound to two antagonistic tetracylated lipid A structural analogs (lipid IVa and Eritoran\textsuperscript{TM}) reveal that MD-2 interacts with its ligands via a hydrophobic pocket which can accommodate at least 4 acyl chains without entailing any conformational change\textsuperscript{5,9-11}. When complexes of MD-2 and TLR4, but not TLR4 alone, are incubated with purified LPS, they produce stable dimers\textsuperscript{5,12}. Consistently, cells expressing TLR4 are activated by purified LPS only when MD-2 is provided as a recombinant protein or a transgene, suggesting that TLR4 activation is downstream from an MD-2 dependent signal which induces its aggregation\textsuperscript{11,13,14}. The most likely scenario for TLR4 activation is that LPS moves from the surface of Gram-negative bacteria to soluble or TLR4-bound MD-2. This movement is promoted by the lipotransferases lipopolysaccharide binding protein (LBP) and CD14. While LBP
and CD14 together may enhance the sensitivity to LPS, neither protein is absolutely required for LPS responses, as cellular activation is reliably observed when a sufficiently high concentration of LPS is employed\textsuperscript{15}. When a phagocyte encounters a Gram-negative cell wall, such high concentrations of LPS are likely. Hence, we speculated that MD-2 might bind to live bacteria and affect the activity of TLR4 on the surface of engaged phagocytes.

In an article recently published in this journal, Tissieries \textit{et al.} reported that MD-2 is an acute phase reactant and binds to heat killed \textit{E. coli}\textsuperscript{16}. In the present work we confirm and extend these observations by presenting a thorough analysis of the binding of MD-2 to live Gram negative bacteria, and by elucidating the role of the MD-2/TLR4 signaling axis during internalization and killing.

**MATERIALS AND METHODS**

\textit{Miscellaneous reagents, recombinant proteins and antibodies}. Unless otherwise specified, reagents were purchased from Sigma. LPS (\textit{E. coli} 0111:B4) was re-purified to remove lipopeptides\textsuperscript{17}. MD-2\textsuperscript{6xHis} and TLR4-Fc were expressed and purified as described\textsuperscript{7,18}. Commercial recombinant MD-2 was from R&D. The antibodies used in this work were: \(\alpha\)-6xHis mAb (Novagen-EMD Biosciences), \(\alpha\)MD-2 mAb (clone 9B4, eBioscience), rat \(\alpha\)-mouse CD11b mAb (Serotec), gold-labeled \(\alpha\)-mouse mAb (Jackson Immunoresearch Labs), HRP-conjugated \(\alpha\)-mouse pAb (Bio-Rad), Alexa\textsuperscript{647}-labeled \(\alpha\)-6xHis mAb (Qiagen), FITC-labeled \(\alpha\)-mouse antiserum (Sigma), and Alexa\textsuperscript{647}-labeled \(\alpha\)-rat antiserum (Molecular Probes).

\textit{Cells}. All mammalian cells were maintained in DMEM supplemented with 10% FBS. 293 and 293\textsuperscript{TLR4-CFP} cells were described previously\textsuperscript{19}. Mouse thioglycollate elicited peritoneal exudate
cells (pΦ) and human PBMCs were harvested and maintained as described in\textsuperscript{20} and\textsuperscript{7}. The \textit{N. meningitidis} (Nm) strains \textit{MC58}\textsuperscript{21}, \textit{H44/76-lpxA}\textsuperscript{22} and GFP-expressing \textit{Nm} (MC58) were grown on chocolate agar (Remel). An acapsular form of \textit{S. agalactiae} (strain 515\textsuperscript{23}) was grown on blood agar plates at 37°C. \textit{Yersinia pestis} (\textit{Yp}\textsuperscript{24}) was cultured at 26°C in tryptose-beef extract (TB) medium with 2.5 mM CaCl\textsubscript{2}. The YFP-expressing strain of \textit{Yp} was generated by electroporation of the Kim5 strain with pYFP (Clontech) and was maintained in ampicillin.

\textbf{MD-2 opsonization, cytofluorimetry and SEM.} \textit{10}\textsuperscript{9} live bacteria were incubated for 30 minutes at 37°C with 20 ng of MD-2\textsuperscript{6xHis} in HBSS/BSA (0.1%, w/v) or with PHS (8% for \textit{Nm} and 30% for \textit{Yp}). Cells were washed thrice and bound MD-2 was detected by FACS using either the Alexa\textsuperscript{647}-labeled \(\alpha\)-6xHis mAb, the \(\alpha\)MD-2 mAb or TLR4-Fc (1 \(\mu\)g/sample) followed by a FITC-labeled \(\alpha\)-mouse antiserum. When indicated, PHS was depleted of MD-2 and reconstituted with MD-2\textsuperscript{6xHis} (20 ng/ml) as described in\textsuperscript{7}. For SEM, MD-2\textsuperscript{6xHis} was detected with an \(\alpha\)-6xHis mAb and a gold-labeled \(\alpha\)-mouse mAb (18 nm gold particles). Cells were fixed and processed for imaging using standard procedures\textsuperscript{11,25}. Images were obtained with a JSM-7401F field emission SEM (JOEL, Peabody, MA) using a backscatter retractable detector.

\textbf{Serum MD-2 isolation and Western blotting.} 15 ml of serum from healthy donors was pre-cleared of immunoglobulins by Protein A-Sepharose beads (PAS) capture, passed through centrifugal concentrators (50-kDa cut-off, Millipore) and incubated with TLR4-Fc coupled PAS beads. Beads were washed with PBS and subjected to SDS-PAGE under reducing conditions. Gels were electroblotted onto nitrocellulose membranes, blocked in PBS/dry milk/0.05% tween-20, and probed with the \(\alpha\)-human MD-2 mAb (1:1000) followed by an HRP-conjugated \(\alpha\)-mouse pAb and ECL (Pharmacia). All incubations were done for 1 hour at r/t.
**Bacteria ELISAs and MD-2 quantitation.** Liquid overnight cultures of Yp were diluted in PBS to the indicated counts and plated in 96-well high protein binding plates. Live bacteria were let adhere for 2 hours at r/t, prior to blocking with PBS/1% BSA/5% sucrose/0.01 Tween-20. 100 µl of human serum (Figure 2C) or MD-2^{6xHis} (20 ng/ml) (Figure 1C) was then added to each well. After washing with PBS-Tween-20, MD-2 on the surface of bacteria was detected with an α-human MD-2 mAb followed by an HRP-conjugated α-mouse pAb and chromogenic reaction. In Figure 1C, MD-2^{6xHis} was titrated on bacteria that were plated at a constant concentration (2×10^7 cells/well). In some experiments, TLR4-Fc (10 µg/ml) was adsorbed on plastic and used to capture soluble MD-2. The concentration of sMD-2 was determined by comparing the absorbance value to a standard curve generated using a commercial recombinant MD-2 (R&D). All incubations were done for 1 hour at r/t unless stated differently. Results are expressed as average of triplicate stimulations +SD.

**Determination of MD-2 binding sites on the surface of bacteria.** MD-2^{6xHis} (20 ng) or whole human sera (input) were incubated with titrated amounts of live bacteria (0 ÷ 2×10^7) in a final volume of 1 ml, for 30 minutes at r/t. Bacteria were centrifuged and MD-2 in the post-cellular supernatants was quantitated by ELISA. The concentration values were used to generate binding isothermes. The number of MD-2 binding sites on the surface of live bacteria was determined by dividing the number of input MD-2 molecules by the number of bacteria that depleted MD-2 from the input. We assumed that bacteria have about 10^6 LPS molecules on the cell surface (C. R. Raetz, personal communication and^{26}).

**Opsonophagocytosis assay.** RAW cells, pМΦ or PBMCs were seeded in triplicate onto 96-well culture plates (5×10^4 cells/well) and infected with fluorescent-protein (GFP or YFP) expressing bacteria (MOI = 40) which were opsonized with MD-2^{6xHis} (20 ng/ml) or PHS (1 ml) as
a source of endogenous MD-2. Plates were centrifuged (200×g for 3 min) in order to ensure proper exposure of phagocytes to the bacteria, and incubated for 30 min at 37°C. Extracellular bacteria were removed and the fluorescence was quantified in the wells. The phagocytosis index was determined by setting the cellular auto-fluorescence to 0 and plotting the average ±SD of all the readings in an arbitrary scale (Arbitrary Fluorescent Units, AFU). In similar experiments, phagocytes were infected with YFP-Yp, fixed and imaged with a Leica TCS SP2 AOBS laser scanning confocal microscope. Cell membranes and nuclei were stained with an α-mouse CD11b mAb (100 ng/sample) followed by an Alexa647-labeled α-rat antiserum and Hoechst 33258 (Invitrogen), respectively.

**Intracellular bactericidal activity.** Opsonophagocytosis was performed as described above. Extracellular bacteria were killed by gentamicin treatment (7.5 µg/ml) for 1 h and cells were cultured in fresh serum free DMEM at 37°C. Six h later, cells were lysed with water and 1/30 of the lysate was plated for colony count (CFU).

**NF-kB luciferase reporter assay.** 293 and 293TLR4CFP bearing a NF-kB-Luc reporter plasmid were infected with the indicated bacteria in DMEM. Luciferase activity was determined as in 7. LPS (0.1 µg/ml) served as a control 27. The readings were normalized by the untreated control and plotted as averages + range of duplicate readings (RLU).

**Cytokines and Nitrite quantitation.** Mouse pMΦ were plated onto 96-well culture plates and infected with live Yp for 24 h. TNF-α and RANTES were quantified using a kit from R&D Systems. Nitrite concentration was determined by Griess reaction using chemicals from Sigma. Results are expressed as average of triplicate stimulations ±SD.
RESULTS

Recombinant MD-2 binds to LPS on the surface of live Gram negative bacteria

Since MD-2 physically binds to the hydrophobic portion of LPS\(^9-11\), we hypothesized that MD-2 binds to the surface of live Gram-negative bacteria due to the high concentration of LPS there. In order to test this hypothesis, we treated two representative Gram-negative organisms, *Neisseria meningitidis* (*Nm*) and *Yersinia pestis* (*Yp*), with a His-tagged recombinant human MD-2 (*MD-2\(^{6\times\text{His}}\)*). Bacteria-bound *MD-2\(^{6\times\text{His}}\)* was then detected by cytofluorimetry. As shown in the upper two panels of Figure 1A, *MD-2\(^{6\times\text{His}}\)* bound to the surface of both organisms, without affecting their viability (data not shown). As negative controls for MD-2 specificity, we used an LPS-negative mutant of *Nm*, H44/76-\(lpxA\)^-, and a non capsulated Gram positive bacterium, *Streptococcus agalactiae* (bottom panels). In both cases, *MD-2\(^{6\times\text{His}}\)* did not bind to the live organisms, suggesting that MD-2 binds specifically to LPS. In addition to its epitope tag, *MD-2\(^{6\times\text{His}}\)* could be detected using both a chimeric protein composed of the extracellular domain of TLR4 and the Fc portion of mouse IgG\(_{\alpha}\) (TLR4-Fc\(^{11}\)) and a monoclonal \(\alpha\)MD-2 antibody\(^{28}\), Figure 1B, suggesting that bacteria-bound MD-2 is not embedded in the bacterial cell wall. The binding of *MD-2\(^{6\times\text{His}}\)* to the surface of live bacteria is specific and saturable, as demonstrated by the titration curves shown in Figure 1C. In these experiments, we either titrated *MD-2\(^{6\times\text{His}}\)* on a fixed amount of adhered bacteria (left panel) or detected titrated bacteria with a fixed amount of MD-2 (20 ng/ml, right panel). *MD-2\(^{6\times\text{His}}\)* appears to be homogeneously distributed on the surface of live Gram negative bacteria, as shown by the scanning electron micrographs of *MD-2\(^{6\times\text{His}}\)-treated Yp* (Figure 1D). Based on our structural knowledge of lipid A, it is reasonable to assume that MD-2 is anchored to the bacterial surface by binding to at least some (1 to 4) of the lipid A’s acyl moieties, leaving the others lipids or other LPS related structures free to anchor the whole LPS:MD-2
complex to the bacterial surface. These results indicate that the binding of recombinant MD-2 to the cell surface of live Gram-negative bacteria is tight (i.e. it resists extensive washing), and can directly bridge the bacterial cell surface to the extracellular domain of TLR4, here in the form of the soluble TLR4-Fc fusion protein.

**Human soluble endogenous MD-2 (sMD-2) binds to the surface of Gram negative bacteria**

We next sought to determine whether soluble serum-derived endogenous MD-2 (sMD-2) binds to live Gram-negative bacteria in a manner similar to its recombinant counterpart. Human serum from healthy donors contains sMD-2\(^7,10,28\). Using a capture scheme based on either protein A sepharose (PAS) immobilized TLR4-Fc or live \(Y_p\) cells, we isolated and visualized endogenous sMD-2 by Western blotting. The pherograms of a representative isolation from one donor are shown in Figure 2A. Consistent with the results obtained with MD-2\(^{6\text{His}}\), serum derived sMD-2 which was captured using TLR4-Fc migrates with two main glycoforms\(^{27}\) (upper panel). Even though MD-2 harbours two N-glycosylation sites, no glycoform appears to bind preferentially to the surface of \(Y_p\) (lower panel), which is consistent with the marginal role that MD-2 glycans play in LPS recognition (refer to\(^6\) for a thorough discussion on this topic). In order to further characterize the binding of serum-derived MD-2 to the surface of live \(Y_p\), we treated the live bacteria with pooled human serum (PHS) and detected bacteria-bound MD-2 by FACS analysis using either TLR4-Fc or an \(\alpha\)-MD-2 mAb. As shown in Figure 2B, both TLR4-Fc and the mAb bound to MD-2 on the surface of live \(Y_p\) (left panels). The signal was lost when we treated bacteria with PHS which was depleted of sMD-2 using TLR4-Fc bound to protein-A sepharose beads\(^7\), middle panels. Reactivity was reinstated by reconstituting depleted PHS with MD-2\(^{6\text{His}}\) (right
panels) and, similar to MD-2<sup>6xHis</sup>, the binding of human sMD-2 to the surface of live <i>Yp</i> was specific and saturable (Figure 2C).

**MD-2 binding to bacterial surfaces is independent of other serum components.**

In order to determine whether serum components influence the binding of MD-2 to the surface of Gram negative bacteria, we calculated the number of MD-2 binding sites on the surface of <i>Yp</i> using recombinant MD-2 in HBSS, and compared it with the number of MD-2 binding sites obtained by using whole sera as a source of MD-2. The number of binding sites was estimated by quantifying MD-2 in the post-cellular supernatants of binding reactions in which the amount of MD-2 was kept constant and bacteria were titrated. Increasing amounts of bacteria were predicted to eventually deplete MD-2 from the post-cellular supernatants. As shown in Figure 3A, about 1.5x10<sup>7</sup> live bacteria were required to deplete 20 ng of MD-2<sup>6xHis</sup>. Twenty ng of MD-2 contain about 4x10<sup>11</sup> molecules of MD-2, which correspond to ~30,000 MD-2 binding sites/bacterium. Using a similar approach we calculated the number of MD-2 binding sites when whole serum was used as a source of sMD-2. In order to provide an accurate determination of the initial concentration of sMD-2 in serum, we developed an MD-2 ELISA in which plastic-bound TLR4-Fc was used to capture sMD-2 and a commercial αMD-2 mAb was used to detect the captured molecule. To further assure inter-experimental and inter-laboratory reproducibility, we used a commercially available MD-2 as a reference for concentration. As shown in Figure 3B, the concentration of sMD-2 in sera from human healthy donors ranged from 2 to 15 ng/ml. These values are consistent with values reported previously (10,28 and T. G. Wolfs, personal communication) and reflect the variability of sMD-2 concentration in human serum. From binding profiles similar to the ones shown in Figure 3C, we calculated that the number of MD-2 binding
sites on the surface of bacteria incubated in the presence of serum averages 30,000 (50,000 ÷ 24,000).

Taken together, the results presented in Figs. 1-3 suggest that soluble MD-2 binds specifically to the surface of Gram-negative bacteria, that other serum components have a marginal effect on this interaction, and that bacteria-bound MD-2 is accessible to cellular TLR4.

**Surface-bound MD-2 enhances bacterial internalization by activating the TLR4/MD-2 signalling axis.**

As the MD-2:LPS complex is the only reported activating ligand for TLR4, we next sought to determine whether bacteria-bound MD-2 affects the biology of TLR4 bearing cells. We established a phagocytosis assay in which YFP-expressing live bacteria were incubated with the phagocytes for 30 min at 37°C in serum free medium (SFM). A phagocytic index was defined as the fluorescence associated with the wells containing infected cells minus the auto-fluorescence of uninfected cells (white bars). As shown in Figure 4A, coating live *Nm* and *Yp* with MD-2^{6His} (black bars) markedly enhanced the phagocytic index in mouse thioglycollate elicited peritoneal exudate cells (p∅), RAW macrophages, and human peripheral blood mononuclear cells (PBMCs). In order to determine whether the increase in the phagocytic index reflected an increased internalization of fluorescent bacteria, and not only an improvement in surface binding, we performed the confocal experiments shown in Figure 4B. Confocal microscopy allows for the detection of fluorescent particles (bacteria) in a two dimensional slice taken from the entire cell body, thus allowing the discrimination of its intracellular or extracellular localization. Both RAW macrophages and pM∅ accumulated an appreciably higher number of bacteria in their cytoplasm when they were infected with MD-2^{6His} treated bacteria.
Since clustering of MD-2 activates TLR4 in 293 cells\textsuperscript{11}, we questioned whether the enhancing effect of bacteria-bound MD-2 was mediated by TLR4 signaling. In order to test this hypothesis, we first employed 293 cells stably transfected with human TLR4 along with an NF-\textkappaB-luciferase reporter gene\textsuperscript{19}. These cells do not activate NF-\textkappaB in response to LPS, unless MD-2 is added as a conditioned supernatant, a transgene or a purified protein\textsuperscript{27}. As shown in Figure 5A, 293\textsuperscript{TLR4} cells that were incubated with \textit{Nm} which was coated with MD-2\textsuperscript{6xHis} markedly induced NF-\textkappaB activity (\textit{Nm} + MD-2\textsuperscript{6xHis}), an effect not seen in untransfected 293 cells (bottom panel). Similar results were obtained with \textit{Yp} (data not shown). As expected, the LPS deficient strain of \textit{Nm}, which does not bind to MD-2, failed to activate the TLR4 expressing cells. Since all the incubations were performed in DMEM without FCS or any other additional serum component, we infer that MD-2 that was bound to the bacterial cell wall aggregated TLR4 on the surface of the reporter cells, thus activating them.

In order to determine the contribution of the TLR4/MD-2 signalling axis in the phagocytic process, we compared pM\textsuperscript{Ф} derived from TLR4-deficient and -sufficient mice. As shown in Figure 5B, MD-2 coating enhanced significantly phagocytosis in wild type cells, where the TLR4/MD-2 axis is intact. On the contrary, MD-2 coating had no effect on the internalization of bacteria by the TLR4-deficient cells. A similar result was obtained with macrophages from the TRIF/MyD88 double knockout mice, in which TLR4 signaling is nearly, if not entirely, abrogated (data not shown) despite the presumed normal expression of surface TLR4. In order to determine the precise role of signal transduction in MD-2 mediated opsonophagocytosis, we examined the uptake of MD-2 coated \textit{Y. pestis} by macrophages from BALB/C mice expressing \textit{Lpsd}, a mutant form of TLR4 in which a point mutation in the TIR domain of the receptor that renders the receptor non-functional. Although \textit{Lpsd} will not signal in response to LPS, the ectodomain of the molecule is expressed and is unaffected by the cytoplasmic mutation. \textit{Lpsd} mutant macrophages
failed to exhibit the enhanced phagocytosis observed in wild-type BALB/C macrophages (Figure 5C). Taken together, these results suggest that the opsonic activity of serum MD-2 requires signal transduction downstream from TLR4 in order to be observed, and involves at least one other surface receptor on macrophages.

**MD-2 opsonization enhances inflammatory phagocytosis via the TLR4/MD-2 signalling axis.**

Since MD-2 treatment affected opsonophagocytosis in a TLR4-dependent manner, we speculated that the internalization of live bacteria would be accompanied by the activation of the phagocytes. In order to test this hypothesis, we determined the content of nitrite (as a measure of bactericidal potential), RANTES (as a representative leukocyte chemoattractant) and TNFα (as a representative proinflammatory cytokine) in the supernatant of infected pMΦ from wild-type, TLR4−/− and MD-2−/− mice. As shown in Figure 6, all the cellular responses examined were markedly enhanced by MD-2 opsonization in the cells derived from the wild-type mouse. The response of TLR4 deficient pMΦ was modest and not affected by MD-2 opsonization, indicating that the TLR4/MD-2 signaling axis is pivotal in the cellular reaction to live Gram negative bacteria such as *Y. pestis*. Not surprisingly, MD-2 deficient cells resembled the TLR4−/− phenotype when bacteria were not opsonized with MD-2 (asterisks), but reacted to the presence of recombinant MD-2 when it was provided on the bacterial surface as opsonin (arrowheads). In contrast to RANTES and TNFα, nitric oxide production in response to live bacteria appeared to be almost entirely dependent on MD-2 opsonization and therefore on TLR4 signaling (Figure 6, bottom left panel).
MD-2 opsonization enhances intracellular killing

In order to test whether the enhancement in cellular activation translates into improved bactericidal activity, we performed gentamicin-protection assays in which the viability of ingested bacteria was assessed after opsonophagocytosis. As shown in Figure 7A, PBMCs killed more efficiently both *Yp* and *Nm* that had been opsonized with MD-2^6His^. In order to exclude any artifactual contribution of gentamicin in the killing of ingested bacteria, we performed opsonophagocytosis experiments with both PBMCs and pMΦ in which extracellular bacteria were washed and no antibiotic was added with comparable results (data not shown). Thus, TLR4 engagement during phagocytosis not only drives a proinflammatory phenotype in the involved cells, but also enhances their bactericidal potential. Opsonization almost doubled bacterial internalization (Figure 4A), and yet, it reduced bacteria viability by more than 60% in the same cells.

In order to study the effect of serum-derived sMD-2 in both opsonophagocytosis and intracellular bactericidal activity, we infected PBMCs with *Yp* in the presence of PHS, Figure 7B (right panel, *Yp*). Compared to the internalization of bacteria in protein-free conditions (left panel), PHS greatly promoted bacterial internalization of untreated *Yp* organisms. This enhancing effect was substantially reduced when PHS was depleted of MD-2 with TLR4-Fc (Figure 7B, right panel, + depleted PHS), an MD-2 dependent outcome that reflects the binding experiments shown in Figure 2. Since phagocytosis was not completely abrogated under conditions known to deplete the activity of MD-2^7^, we surmised that MD-2 produced by the phagocytes themselves contributed to the phagocytic process. In order to address this point, we used macrophages from MD-2^−/−^ mice and performed similar opsonophagocytosis experiments, Figure 7C. MD-2-deficient cells were efficiently complemented by both MD-2^6His^ (*Yp* + MD-2, left panel) and serum-derived MD-2
(Yp, right panel). MD-2 depletion from PHS reduced substantially the internalization of live bacteria (Yp + depleted PHS, last bar). Taken together, these results suggest that both human sMD-2 present in PHS and recombinant MD-2 contribute to the phagocytic process. In addition, endogenous sMD-2 (PHS) appeared to enhance the killing of internalized bacteria, as shown in Figure 7D. In these experiments, MD-2 deficient phagocytes were infected with Yp (or Nm, not shown) in the presence of PHS (open bars) or in serum free conditions (black bars). The amount of intracellular killing which was mediated by either sMD-2 containing PHS or MD-2<sup>6His</sup> opsonization was consistently higher than that obtained by infecting the cells in SFM.

**DISCUSSION**

The main novel findings presented in this paper are: i) approximately 30,000 molecules of MD-2 (recombinant or serum derived) bind specifically to LPS on the surface of live Gram-negative bacteria, ii) MD-2 binding to Gram-negative bacteria is resistant to extensive washing, and iii) phagocytosis and intracellular killing of MD-2-opsonized bacteria depend on TLR4 signaling. Considering the soluble nature and the distribution of sMD-2 (~ 10 ng/ml or 0.3 nM in human serum), it is reasonable to assume that MD-2 is among the first components that a microbe encounters after breaching the body’s physical barriers. Based on the data presented here, sMD-2 is anticipated to be a central player in the antibacterial defense program in mice and humans. However, our studies raise the issue of whether the pro-opsonophagocytic effect of sMD-2 is physiologically relevant, since the reaction to a pathogen in vivo relies on many complex dynamic systems in interaction with each other. In order to establish a reciprocal connection between the in vitro experimental findings and the biological role of MD-2 in the whole organism, one would need to study individuals in which MD-2 activity or expression levels are impaired. Since there is
no reported condition linked to such deficiencies, this question cannot be answered directly in humans. Nevertheless, traditional reductionistic laboratory methods are the best way of testing simple causal theories because they allow for the manipulation of a limited set of interdependent variables that influence both the outcomes and each other. For this reason, we developed and performed opsonophagocytosis assays in protein-free conditions in order to detect only very strong effects, which are likely to be physiologically relevant. It is imperative to emphasize that under the defined conditions used in this work, MD-2 opsonization more than doubled bacterial internalization (Figure 4A and 8A), and yet, it enhanced intracellular killing by more than 60% in the same cells (Figure 7). Therefore, the effect of MD-2 opsonization appears to be even more dramatic when it is considered in absolute terms. In addition, the PHS depletion experiments employing MD-2 deficient phagocytes (Figure 8) demonstrate that sMD-2 (and not cellular MD-2) can account for about 50% of the entire phagocytic and killing activities even in the presence of soluble serum factors. Finally, the presence of soluble MD-2 in normal human serum (and other biological fluids such as milk, tears and urine, and in the serum of chimpanzee and *Macacus rhesus* (VJ and AV unpublished observations)) further supports a physiological role for soluble MD-2 in the antibacterial defenses of primates, rodents and presumably, mammals in general.

Mouse and human phagocytes are known to express simultaneously both TLR4 and MD-2. The interaction between TLR4 and MD-2 is non covalent, hence TLR4 interacts with MD-2 in accordance to the law of mass action. The calculated $K_d$ for this interaction is about 12 nM$^{7,27}$. This implies that, independent of the source of MD-2 (the same TLR4 expressing cell or the interstitial/extracellular fluids), less than 50% of the total TLR4 on the cell surface is expected to be saturated with MD-2 at chemical equilibrium, because the $K_d$ of this interaction is about 40 times higher than the concentration of sMD-2 in serum. Therefore, a large proportion of cellular TLR4 is expected to be available for the binding to bacteria-associated MD-2. Since we could not
detect LPS dependent differences in the $k_d$ of the TLR4-Fc:MD-2 equilibrium, a first order binding kinetic of non-cooperative binding appears to govern the interaction between TLR4 and LPS-ligated or -free MD-2. Accordingly, the binding affinity of TLR4 for MD-2 is predicted to increase if TLR4 clusters upon binding to patched MD-2, in a manner that is reminiscent of the interaction of the Fc gamma receptor with aggregated immunoglobulins. Consequently, it is conceivable to assume that bacteria-clustered MD-2 has the ability of displacing MD-2 which is pre-bound to TLR4.

The sparse and homogeneous distribution of MD-2\textsuperscript{6xHis} on the surface of bacteria shown in the SEM micrographs of Figure 1D, is likely to reflect the harsh conditions used in the preparation of these samples. In fact, we estimated that the surface of live $Y_p$ bears about 30,000 MD-2 docking sites, roughly corresponding to one molecule of MD-2 per 33 molecules of LPS, assuming that bacteria have approximately $10^6$ molecules of LPS on their surfaces. Considering the steric hindrance of MD-2 toward LPS, and the presence of other surface structures and proteins that require LPS solvation, the mechanism of MD-2 binding to LPS in the outer layer of the bacteria wall can only be hypothesized. We favour a model in which the bacterial surface provides a platform on which MD-2 is layered homogeneously and exposes most of its surface to TLR4. This view is consistent with the observation that two mAbs and TLR4-Fc combine with bacteria-bound MD-2, Figure 1 A-B. The results presented in this work also suggest that at least two complementary modes of LPS recognition and TLR4 activation exist, depending on whether LPS is partially embedded in the cell wall or it is delivered to MD-2 as a soluble molecule. In the first case (as presented here), the binding appears to be independent of serum components. MD-2 is likely to bind only to a fraction of the available lipids of any given lipid A moiety, probably allowing the others to maintain cell wall anchorage. As a consequence, surface patterned MD-2 passively aggregates TLR4 which in turn initiates an activating signal on the phagocytes. This
model is consistent with the structure of the TLR4:MD-2 complex, in which the ligand binding cavity of MD-2 appears to be directed opposite to its TLR4 interacting surface\(^5\). In the second scenario, multiple MD-2 molecules (most likely two, AV data not shown) gain access to the whole complement of lipid A’s acyl chains thus generating a TLR4 activating ligand. Although we could not exclude that TLR4 activation occurred as a consequence of the release of MD-2:LPS complexes from the bacteria during the phagocytic process, our results are consistent with the idea that opsonized live bacteria induce the activation of TLR4 in the developing phagosome and ensure that the “danger” signal associated with the presence of LPS is delivered in the very same phagocytic compartment in which killing, antigen processing and presentation ought to be promoted, as proposed by Blander and Medzhitov\(^{32,33}\). An additional implication of these findings is that during phagocytosis of live bacteria, which are a good source of freshly produced ATP, both ATP and PAMPs are concentrated together in the phagosome and can find their way to the cytosol, thus providing optimal conditions for the activation of the inflammasome\(^ {34}\).

We observed that both TLR4 and MD-2 are an absolute requirement for mediating pro-inflammatory opsonophagocytosis of Gram-negative bacteria. This is in contrast with previously published results suggesting that the effect of MD-2 is observed only at early time points (<20 minutes)\(^ {16}\). Although the overall conclusions of both the works are overlapping, we believe that the difference might be due to the fact that we used live bacteria and phagocytes from gene targeted animals, whereas Tissieres et al. used lyophilized bio-particles and antibody inhibition of TLR4 for their phagocytosis assays. Thus, the two systems are hardly comparable.

Intuitively, it might be assumed that blocking MD-2 activity is beneficial in LPS-related conditions such as the sepsis syndrome. This notion has been supported by a variety of reports, including one from our group\(^ {7,35}\). At the same time, an early MD-2/TLR4 dependent “innate”
reaction to the presence of Gram negative bacteria is undisputedly a pivotal defense mechanism, since a strong TLR4 response is necessary and sufficient in order to overcome the totality of the multifaceted virulence armamentarium that an organism like *Y. pestis* can deploy. The results presented in the present work provide a rationale for the latter observation, and demonstrate that interfering with MD-2 activity might be detrimental in the earliest stages of exposure to Gram negative bacteria. Understanding how serum components such as MD-2 direct and modulate the fate of the phagocytic cargo might inspire novel strategies for developing efficient therapeutic and prophylactic interventions aimed at accelerating pathogen clearance and altering the course of infection.

ACKNOWLEDGEMENTS

We wish to acknowledge Drs. Steeghs and van der Ley (Netherlands Vaccine Institute, Bilthoven, The Netherlands) for providing us with the *Nm* H44/76-*lpxA* strain, Dr. Agarwal for the GFP-*Nm* strain, Dr. Viriyakosol for the MD-2<sup>6xHis</sup> baculovirus and Dr. Wozniak for helping with mouse experiments. We are also indebted to Drs. Akira and Miyake and the Japan Science and Technology Agency, for providing us with the TLR4 and MD-2 knockout mice, respectively. The NIH supported all the authors of this manuscript with the grants AI069084 (AV and VJ), RO1GM54060 (DTG, KAH and AH), AI057588 (EL), AI054544 (SR) and AI052455 (MCD).

**Disclosure:** The authors declare no conflict of interest.

**Contributions:** AV supervised the project; AV, VJ and DTG designed research and analyzed the results; VJ performed all the experiments; AH helped with producing SEM and confocal micrographs; KAH and AV produced critical reagents; EL, MCD, SR provided bacterial strains; AV, VJ and DTG wrote the paper; AV and DTG contributed equally to this work.
FIGURE LEGENDS

**Figure 1. Recombinant MD-2 binds to live bacteria.** (A) The indicated live bacteria were left untreated (shaded profiles) or were opsonized with MD-2\(^{6\text{His}}\) (solid line) and subjected to cytofluorimetry using an Alexa\(^{647}\)-labeled \(\alpha\)-6xHis mAb. The *Nm lpxA* strain is LPS negative. (B) Live *Yp* cells were incubated with MD-2\(^{6\text{His}}\), and surface-bound MD-2 was detected by cytofluorimetry using either TLR4-Fc or an \(\alpha\)MD-2 mAb followed by a FITC-labelled \(\alpha\)-mouse antiserum (solid line profiles). The shaded profiles represent the binding of the secondary reagent without MD-2 coating. Fluorescence intensity is plotted in a log scale (x-axis, 10\(^{-5}\)). (C) Live *Yp* were adsorbed to high protein binding plates in either fixed amounts (2x10\(^7\)/well, left) or in twofold dilutions (right). MD-2\(^{6\text{His}}\) was then applied to the wells in twofold dilutions (left) or in a fixed amount (20 ng/ml, right). MD-2 bound to adsorbed bacteria was detected by ELISA using an \(\alpha\)MD-2 mAb. Results are shown as the average +SD of triplicate absorbance readings at 450 nm. (D) *Yp* (Kim5) was left untreated (left panel) or was incubated with MD-2\(^{6\text{His}}\) as in A (right panel). MD-2\(^{6\text{His}}\) was stained with an \(\alpha\)-6xHis mAb and imaged by SEM. Shown are the back scatter images of two random fields acquired at 8,000x. White bar = 1 \(\mu\)m.

**Figure 2. Human serum-derived MD-2 binds to bacteria.** (A) PAS conjugated TLR4-Fc or live *Yp* cells were used to precipitate MD-2 from the serum of a healthy individual or 15 ml of baculoviral supernatants containing MD-2\(^{6\text{His}}\) as a positive control. The pellets were washed and Western blotted for the presence of MD-2 using a commercial \(\alpha\)MD-2 mAb, followed by an HRP-conjugated \(\alpha\)-mouse antiserum and ECL. The 160 kDa band in the uppermost panel is TLR4-Fc which is recognized by the \(\alpha\)-mouse antiserum. Similar results were obtained with two other healthy donors. Vertical lines have been inserted to indicate repositioned gel lanes. (B) Live *Yp*
cells were stained with pooled human serum (PHS, left panels), PHS that was depleted of MD-2 using TLR4-Fc (middle panels), and depleted PHS that was reconstituted with recombinant MD-2 (20 ng/ml, right panels). Bound MD-2 was detected by FACS using either TLR4-Fc (upper panels) or an αMD-2 mAb followed by a FITC-labeled α-mouse pAb. The shaded profiles represent the binding of the secondary reagent without MD-2 coating. Fluorescence intensity is plotted in a log scale (x-axis, 10−105). (C) Bacteria were adhered to plastic in twofold dilution and incubated with PHS. Human serum-derived soluble MD-2 bound to the surface of the bacteria was revealed by ELISA as in Figure 1C.

**Figure 3. Binding of MD-2 to the surface of \( Yp \) is independent of serum components.** (A) The indicated amounts of live bacteria (x-axis) were incubated in HBSS with a fixed amount of MD-2\(^{6\text{His}} \) (input). MD-2 in the post-cellular supernatants (Y axis) was quantitated by ELISA (see B) and plotted as a function of the number of bacteria used in the binding reaction (x axis). About \( 10^7 \) bacteria were necessary to deplete 20 ng of MD-2\(^{6\text{His}} \) input, which corresponds to about 40,000 MD-2 binding sites on the surface of \( Yp \), assuming that bacteria have \( 10^6 \) molecules of LPS on their surfaces. Plotted values are the average of two independent experiments ± range. (B) Soluble MD-2 form the serum of healthy donors (n = 10) was determined by ELISA using plastic adsorbed TLR4-Fc to capture sMD-2 and a commercial αMD-2 mAb as detection reagent. (C) Binding isothermes were generated as in A, but here human serum was used as a source of sMD-2. Plotted are sera from three representative donors. Error bar is the SD of triplicate determinations.

**Figure 4. MD-2 enhances opsonophagocytosis.** (A) Adherent pMΦ, RAW macrophages or PBMCs were infected for 30 min with untreated (grey bars) or MD-2\(^{6\text{His}} \) opsonized (20 ng/ml, black bars) fluorescent-protein expressing live \( Nm \) and \( Yp \). Shown is the average fluorescence of triplicate wells ±SD. Fluorescence Units were plotted on an Arbitrary scale (AFU) and cellular
auto-fluorescence (white bars) was set to 0 (Phagocytic index). (B) RAW macrophages or mouse pMΦ were incubated with YFP-Yp as in A and were subjected to confocal microscopy. Nuclei were stained with Hoescht 33258 (blue) and the cell surface was stained with an α-CD11b (red).

*Nm, N. meningitidis; Yp, Y. pestis.*

**Figure 5. The pro-phagocytic effect of MD-2 is mediated by TLR4.** (A) 293 cells expressing TLR4 and a NF-κB-luciferase reporter plasmid were stimulated with live *Nm* (MC58) or with *Nm lpxA* which had been treated as indicated (Y axis). Luciferase readings were normalized by the activity of unstimulated cells (RLU = 1). Shown are the averages of duplicate points + range. LPS served as control. A similar experiment was performed with 293 cells (bottom panel). (B) pMΦ from TLR4−/− (open bars) or wild type (black bars) mice were infected with GFP-*Nm* or YFP-*Yp* which were processed for the phagocytosis assay as in Figure 4A. Note that MD-2 coating exerts no effect on TLR4−/− cells. (C) pMΦ from the BALB/C (*Lps*wt) and C3H/HeJ (*Lps*Δ) mice were infected with non opsonized (grey bars) or MD-26xHis coated YFP-*Yp* and subjected to fluorescent opsonophagocytosis assay as in C. These experiments were repeated at least three times with similar results. *Nm, N. meningitidis; Yp, Y. pestis.*

**Figure 6. MD-2 opsonization enhances cytokine and nitrite production.** pMΦ from wild type (leftmost panels), TLR4 (middle panels) and MD-2 mice (right panels) were left untreated (white bars) or treated with LPS (dark grey bars), live *Yp* (light gray bars) or MD-2-coated *Yp* (black bars). RANTES, TNFα and Nitrite concentrations were determined from the same supernatants by ELISA. The arrowheads indicate the restoration of the “wild-type” phenotype in MD-2+ cells, when MD-2 is provided on the surface of bacteria. In the absence of MD-2 treatment, MD-2 deficient pMΦ resemble the TLR4 knockout phenotype (asterisks). Results are the average of triplicate readings +SD and the experiment is representative of three.
Figure 7. **MD-2 opsonization enhances phagocytosis and intracellular killing.** (A) Human PBMCs were incubated for 30 min with *Yp* and *Nm* which were left untreated or were opsonized with MD-2^6xHis_. Extracellular bacteria were killed by gentamicin treatment and cells were chased for 6 additional hours in DMEM. Viability of internalized bacteria was assessed by colony count (CFU) and plotted as the average of duplicate determinations + range. Similar results were obtained with PBMCs from two other unrelated donors. (B) Adherent PBMCs were infected with either untreated or MD-2^6xHis_ opsonized YFP-*Yp* in the absence (SFM) or presence of 30% pooled human serum (PHS). Samples were processed and plotted as in Figure 4A. Note the scale difference between the two panels. (C) pMΦ from the MD-2^{−/−} mouse were treated as in A. (D) pMΦ from the MD-2^{−/−} mouse were infected with untreated or MD-2^6xHis_ opsonized *Yp* in the presence (white bars) or absence (black bars) of PHS. Colony count and plotting of live phagocytosed bacteria was performed as in Figure 7. These experiments were repeated at least three times with similar results.
