Abstract

Acquired hemophilia A is a rare bleeding diathesis caused by autoantibodies directed against clotting factor VIII and associated with an increased morbidity and mortality. This autoimmune disorder most commonly occurs in the elderly. Although it may be associated with several underlying pathologies, up to 50% of reported cases remain idiopathic. In contrast with congenital hemophilia, which is commonly characterized by hemarthroses, hemorrhages in patients with acquired hemophilia involve most frequently soft tissues. The two treatment priorities are to arrest the acute bleeding and to eradicate the factor VIII autoantibody. Acute bleeding episodes in patients with low-titer inhibitors can be treated using human factor VIII concentrates, whereas factor VIII bypassing agents, such as activated prothrombin complex concentrates or recombinant activated factor VII, are effective for the treatment of those with high-titer inhibitors. An analysis of the literature shows that the most effective first-line treatment for the eradication of factor VIII autoantibodies is the combination of steroids and cyclophosphamide. However, there is increasing evidence on the effectiveness of other treatment approaches, such as immune tolerance regimens and rituximab. If confirmed by large controlled studies, these innovative therapies might become a valid option for long-term eradication of factor VIII inhibitors.

Key words: autoantibodies, factor VIII, hemophilia, inhibitors.
Introduction

Acquired inhibitors against factor VIII (FVIII), also termed acquired hemophilia A, occur rarely in the non-hemophilic population, with an incidence of approximately 1-4 per million/year.1-9 Although uncommon, these autoantibodies are associated with a high rate of morbidity and mortality as severe bleeds occur in up to 90% of affected patients and the mortality rate is high, ranging from 8% to 22%.10-12 For these reasons, patients with acquired hemophilia A represent a demanding clinical challenge.

The incidence of acquired hemophilia A increases with age, being a very uncommon condition in children.13 Indeed, the incidence in children under 16 years has been estimated to be 0.045 per million/year compared with 14.7 per million/year in the elderly aged over 85 years.9 However, it is also likely that the incidence of this autoimmune disorder is significantly underestimated, especially in elderly patients. The age distribution of autoantibodies is typically biphasic with a small peak between 20 and 30 years, due to postpartum inhibitors, and a major peak in patients aged 68-80 years. The incidence in men and women is similar except in the age ranges 20-40 years where the effect of pregnancy results in a preponderance in women.6 In approximately 50% of cases, FVIII autoantibodies occur in patients lacking any relevant concomitant disease, while the remaining cases may be associated with postpartum period, autoimmune diseases, underlying hematologic or solid cancers, infections or use of medications (see Table 1).14-29

The bleeding pattern of acquired hemophilia A is rather different from that of congenital hemophilia A. Thus, most patients with FVIII autoantibodies have hemorrhages into the skin, muscles or soft tissues and mucous membranes (e.g. epistaxis, gastrointestinal and urological bleeds, retroperitoneal hematomas, post-partum bleeding), whereas hemarthroses, a typical feature of congenital factor VIII deficiency, are uncommon.5,10 The hemorrhages are often serious or life-threatening and the disease may manifest more dramatically by excessive bleeding following trauma or surgery or by cerebral hemorrhage.6
The diagnosis of acquired hemophilia A in a patient with no previous personal or family history of bleeding is typically based on (i) the initial detection of an isolated prolongation of activated partial thromboplastin time (APTT), which cannot be corrected by incubating for 2 hours at 37°C equal volumes of patient plasma and normal plasma (mixing study), and (ii) subsequent identification of a reduced FVIII level with evidence of FVIII inhibitor activity (titrated using the Bethesda assay or its Nijmegen modification).1

The epidemiology, pathogenesis, clinical associations and diagnosis of acquired hemophilia A has been extensively reviewed elsewhere,1-7 so in this review we will focus on the current treatment of this autoimmune hemorrhagic disorder.

**Treatment of acquired FVIII inhibitors**

The appropriate pharmacological treatment of patients with acquired hemophilia depends essentially on the natural history of any concomitant pathology and the clinical presentation of coagulopathy.30-32 The fundamental aspects of therapeutic strategy in patients with acquired hemophilia A are the treatment of acute bleeding episodes and the long-term eradication of the autoantibody (see Table 2). On the other hand, the cure of the possible associated disease is also important as, in some cases, it will lead to the disappearance of the inhibitor.33

Finally, we must outline that the next chapters report our own approach to the treatment of this syndrome, all primarily based on our personal experience and subjective interpretation of the available literature data, which is sparse on adequately powered, prospective, randomized and controlled trials.

**Treatment of acute hemorrhages**

Two options are currently available for haemostatic control of acute bleeding: the use of bypassing agents and strategies aimed to raise the level of circulating FVIII. The choice of the most appropriate therapeutic strategy will depend on the site and severity of the bleeding and the
inhibitor titer. Of note, any potential additional risk situation for bleeding, such as intramuscular injections, invasive procedures or the use of antiplatelet agents, should also be avoided.

**Bypassing agents**

Bypassing agents are currently the most used first-line treatment and both the recombinant activated factor VII (rFVIIa) and the activated prothrombin complex concentrate (aPCC) factor eight inhibitor bypassing activity (FEIBA) have been proven to be effective in the treatment of acquired hemophilia A. As regards the latter, a large retrospective study conducted by Goudemand and the French FEIBA Study Group reviewed the use of FEIBA for the treatment of 55 bleeding events in 17 patients with acquired hemophilia. At a median dosage of 68 U/kg (range, 35-80 U/kg) administered every 8-24 hours for a median of 3.5 days (range 1-17 days), FEIBA was found to provide an excellent or good hemostatic efficacy in 89% of the bleeding episodes. Sallah retrospectively analyzed the efficacy of FEIBA in 34 patients with acquired haemophilia, the majority of whom received a dose of 75 U/kg every 8-12 h. A complete response was achieved in 76% of severe and 100% of moderate bleeding episodes, for an overall complete response rate of 86%. Holme and colleagues reported the Norwegian experience with FEIBA in acquired hemophilia. The hemostatic efficacy of this bypassing agent, administered at a dosage of 70 U/kg every 8 h, was judged to be excellent in all eight severe bleeds treated. Thus, based on the literature, the recommended dose of aPCC ranges between 50 and 100 IU/kg administered every 8-12 hours.

The first large experience on the use of rFVIIa in patients with acquired hemophilia comes from Hay and colleagues, who published a multicenter retrospective analysis of 38 patients treated for 74 bleeding episodes with rFVIIa. The average starting dose was 90 µg/kg (range 45-181 µg/kg) every 2-6 hours, while a median of 28 doses (range 1-541 doses) were given per episode, over a median 3.9 days (range 0-43 days). The authors reported a good response in 100% of patients when rFVIIa was used as a first-line treatment, and a good response in 75% of patients when it was used as salvage therapy. Recently, Sumner and colleagues collected the available data on the use of rFVIIa in acquired hemophilia patients from compassionate use programs, the Hemophilia and...
Thrombosis Research Society (HTRS) Registry and from the published literature. A total of 139 patients were treated with rFVIIa for 204 bleeding episodes. The overall efficacy rate (complete or partial) of rFVIIa was 88% (161/182 bleeding episodes evaluable). rFVIIa as a first-line treatment was effective overall in 95% of bleeding episodes compared with 80% when it was used as salvage therapy after failure of other hemostatic agents. Interestingly, in order to overcome the short half-life of rFVIIa (approximately 2.5 hours), some pharmaceutical industries are developing rFVIIa molecules with an extended half-life obtained with pegylated formulations or with the fusion of FVIIa to human albumin.40,41

Although there are no comparative studies on the efficacy and risk of adverse events of aPCC and rFVIIa for the management of acute bleeds in acquired hemophilia patients, personally we prefer the latter due to its viral safety (i.e., recombinant product) and its excellent safety and efficacy profile.42 We recommend a intravenous bolus dose of 90-120 µg/kg repeated every 2-3 hours depending on the clinical response. Although continuous infusion of rFVIIa is an interesting alternative to bolus injection, and which has been explored in order to simplify the method of administration and to reduce the costs,43,44 it is not yet well standardized and officially registered.

Treatments to raise FVIII levels

Regarding possible therapeutic strategies aimed to raise the levels of circulating FVIII, plasma-derived porcine FVIII, which has been successfully used in the past to achieve hemostatic levels in situations where human FVIII was ineffective, is not currently available for routine clinical use.45,46 However, a recombinant B domain deleted porcine factor VIII (OBI-1) has recently been tested in a phase II open-label study in congenital hemophilia A patients with inhibitors.47 Given the promising results of this study, OBI-1 could also be tested in trials on patients with acquired FVIII inhibitors. Human FVIII concentrates usually represent an inadequate hemostatic therapy unless the inhibitor titer is low (i.e., less than 5 Bethesda Units [BU]). Patients with low titer inhibitors can be treated with plasma-derived or recombinant human FVIII concentrates, which should be administered at doses sufficient to overwhelm the inhibitor and thus achieve hemostatic levels of factor VIII.32
While a number of formulae have been proposed for calculating the optimal dose of FVIII to administer, the inaccuracy inherent in the laboratory measurement of inhibitor titers in acquired hemophilia makes these very approximate tools and thus regular monitoring of plasma FVIII levels and clinical response are required. Accordingly, we recommend an intravenous bolus dose of 20 IU/Kg for each BU of the inhibitor plus 40 additional IU/Kg, and the monitoring of FVIII activity (FVIII:C) levels 10 minutes after the initial dose, and the subsequent administration of an additional bolus dose if the incremental recovery is not adequate.

Some hemophilia centers use human FVIII concentrates in association with immunoadsorption in order to reach hemostatic FVIII levels despite high initial anti-FVIII inhibitor titers. Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP) alone or in association with human FVIII concentrates may also be effective in patients with a low titer of inhibitor for the treatment of minor bleeding episodes.48 We have documented a positive experience on the use of DDAVP alone, at a dose of 0.3 µg/kg/day given subcutaneously for 3-5 days, in a series of patients with low inhibitor titer for the treatment of non life-threatening hemorrhages (hematomas, mucosal hemorrhages, hemarthroses) or for hemostatic coverage of invasive procedures.49,50

Inhibitor eradication

The elimination of the FVIII autoantibody may be achieved through various therapeutic options, which have been variably combined, including immunosuppressive agents (steroids, cytotoxic drugs such as cyclophosphamide, azathioprine and vincristine, cyclosporine and rituximab [see next section]), high dose intravenous immunoglobulin (IVIG), immunoadsorption, and immune tolerance.6,32

Immunosuppressive agents

While a number of studies have been published on the immunosuppressive therapy of patients with acquired hemophilia, the great majority of them are case reports or small single center retrospective surveys. In the only randomized prospective trial available on this subject in the literature,51 31
patients were initially treated with prednisone alone at a dose of 1 mg/kg/day for 3 weeks. If the autoantibody was still detectable, the patients were then randomized to receive for additional 6 weeks prednisone alone, prednisone with oral cyclophosphamide (2 mg/kg/day), or cyclophosphamide alone. Approximately one third of the patients responded to the initial prednisone course, while approximately 50 percent of the steroid-resistant patients responded to cyclophosphamide-containing regimens. In a case series published by Shaffer and Phillips,\(^{52}\) the association of oral cyclophosphamide and prednisone was successful in achieving a complete remission (CR) in all the 9 consecutive acquired hemophilia patients enrolled. A non-randomized study conducted by the United Kingdom Haemophilia Centre Doctors’ Organization (UKHCDO)\(^9\) did not find a significant difference among the groups treated with steroid alone or with a combination of steroids and cytotoxic (76% versus 78%). In their meta-analysis, combining data from 20 reports, Delgado and colleagues\(^1\) concluded that cyclophosphamide use was superior to that of prednisone in terms of inhibitor eradication but not in terms of overall survival. The combined data available from uncontrolled cohort studies recently reviewed by Collins, suggested a benefit for combined steroids and cytotoxic agents.\(^{32}\) Other combinations, such as prednisone with azathioprine or prednisone with cyclophosphamide and vincristine were also proven effective.\(^{53,54}\)

Thus, on the basis of the available literature and our personal experience, we usually prefer to start inhibitor eradicating therapy with prednisone (1 mg/kg/day) and cyclophosphamide (1-2 mg/kg/day) for at least 5 weeks. However, we must emphasize that immunosuppressive therapy should be strictly tailored to the patients’ characteristics (i.e., age, sex and general health status) in order to minimize the treatment-related adverse effects.\(^{55}\) Indeed, an analysis of the data from the European Acquired Hemophilia Registry (EACH) showed that infections related to immunosuppressive therapy were the first cause of death in patients with acquired hemophilia (unpublished data). Similarly, in the meta-analysis conducted by Delgado and colleagues\(^1\) and including 249 patients, a substantial proportion of patients receiving cyclophosphamide, especially elderly, died as a result of complications related to this agent, mainly neutropenia-related infections.
Thus, cyclophosphamide and other alkylating agents should be used cautiously in elderly patients, due to the increasing rate of side-effects. Indeed, we usually reduce the dose and duration of cyclophosphamide treatment (i.e., 50 mg/day for 3-4 weeks) in these patients. Furthermore, these cytotoxic agents avoided in women of reproductive age, as they may cause infertility. As a consequence, we usually start first-line eradicating therapy.

Finally, cyclosporine, at a dose of 200-300 mg/day alone or in combination with steroids, has been used successfully as a salvage therapy.\textsuperscript{56,57}

\textit{High dose intravenous immunoglobulin}

Intravenous immunoglobulin (IVIG) are derived from the pooled plasmas of thousands of blood donors and contain anti-idiotypic antibodies directed against FVIII inhibitors.\textsuperscript{5} The first report on the successful use of high dose IVIG in patients with acquired hemophilia comes from Sultan and colleagues.\textsuperscript{58} In a subsequent prospective multicenter study evaluating the efficacy of high-dose IVIG in acquired FVIII inhibitors a rather low response rate of between 25\% and 37\% was observed, with complete remissions occurring almost exclusively with low titer inhibitors.\textsuperscript{59} A study of six patients treated concomitantly with steroids and IVIG reported a CR rate of 66\%.\textsuperscript{60} However, a literature review of acquired hemophilia patients treated with IVIG with no concomitant immunosuppressive treatment was disappointing, as only a 12\% CR rate was observed.\textsuperscript{61} Finally, a recent study comparing patients who either did or did not receive IVIG showed no benefit for IVIG.\textsuperscript{9} Thus, the current clinical results indicate that high dose IVIG are not useful as a first choice for the suppression of FVIII autoantibodies, but may play a role as adjunctive therapy to other inhibitor eradicating treatments (steroids, immunoadsorption, immune tolerance regimens). The usual administered dose is 2 g/kg for 2 consecutive days or 0.4 g/kg for 5 consecutive days. As IVIG are well tolerated and with few toxic effects, they are particularly suitable as an adjunct therapeutic option for elderly patients with acquired FVIII inhibitors.\textsuperscript{39}
Immunoadsorption

Exchange plasmapheresis has been used for many years for a temporary, rapid extracorporeal removal of the autoantibody, especially in cases of severe bleeding associated with high titer inhibitors. The introduction of immunoadsorption techniques, including sepharose-bound staphylococcal protein A and sepharose-bound polyclonal sheep antihuman antibodies, has increased the volume of plasma processed and the efficacy of the procedure. The transitory drop of the inhibitor titer permits replacement therapy with human FVIII concentrates, which must then be administered immediately after the treatment cycle to achieve hemostasis. Immunoadsorption has also been used in the setting of immune tolerance protocols (see below). The main limits of this technique are that it is costly and technically demanding. For this reason it is performed only in specialized centers.

Immune tolerance

Immune tolerance (IT) protocols, like those successfully used for the treatment of alloantibody inhibitors in patients with congenital hemophilia, have also been proposed for the eradication of FVIII autoantibodies. The rationale for the use of IT in acquired hemophilia is that the stimulation of the immune system by exogenous FVIII infused increases the susceptibility of the inhibitor-producing B-cell clones to the effect of cytotoxic agents. In the case report published by Green in 1971, high doses of FVIII and intravenous cyclophosphamide were given simultaneously to successfully treat a patient with an acquired FVIII inhibitor unresponsive to combined immunosuppressive treatment. In a later report, Lian and colleagues treated 12 patients with cyclophosphamide, vincristine and prednisone obtaining CR in all but one patient. The Budapest protocol, consisting of 3 weeks of treatment with a combination of human FVIII concentrates (30 IU/kg/day for the first week, 20 IU/kg/day for the second week and 15 IU/kg/day for the third week), intravenous cyclophosphamide (200 mg/day for a total dose of 2-3 g) and intravenous methylprednisolone (100 mg/day for the first week, tapering the dose gradually over the next 2 weeks), resulted in a eradication of autoantibody in more than 90% of treated cases. Similarly, the
modified Bonn-Malmö protocol, including a combination of oral cyclophosphamide (1-2 mg/kg/day), prednisolone (1 mg/kg/day), large-volume immunoadsorption (2.5-3.0 times the plasma volume on days 1-5 weekly), high dose IVIG (0.3 g/kg on days 5-7 weekly) and FVIII concentrates (100 IU/kg/day), obtained a rapid (median 14 days) and complete remission in 88% of patients. Although undoubtedly of interest, positive results of immune tolerance protocols so far reported are only preliminary and need to be validated by further large controlled studies before they can be considered as a first-line treatment for patients with acquired hemophilia A.

**Novel eradicating therapies: rituximab**

Rituximab is a monoclonal antibody (against the pan B cell antigen CD20) which induces a rapid in vivo depletion of normal B lymphocytes. Although this agent was originally developed for the use in patients with B cell non-Hodgkin’s lymphomas, its use has been successfully extended to many autoimmune disorders. Indeed, biotherapy with the rituximab has been also used to treat cohorts of patients with acquired hemophilia. Wiestner and colleagues described three patients with high titer FVIII autoantibodies who experienced rapid and durable responses following treatment with rituximab alone or in association immunosuppressive therapy. The largest published study reported on 10 patients and documented CR in eight of them whereas the two non-remitters responded to subsequent intravenous cyclophosphamide. Three relapsed patients, with inhibitor titers higher than 100 BU, obtained a new sustained remission after re-challenge with the same cycle of rituximab. Since then, a number of case reports have described patients with acquired hemophilia refractory to first-line immunosuppressive treatments who responded to rituximab. Aggarwal and colleagues treated four patients with autoimmune hemophilia and high titer inhibitors with rituximab and observed durable complete response in two of them. The other two patients initially responded, but relapsed at 3.5 and 8.5 months, respectively. However, both responded to second courses of rituximab and prednisone. Thus, based on their own positive experience, the authors proposed a treatment algorithm with the use of rituximab in association with
immunosuppressive agents as first-line treatment in patients with high titer FVIII autoantibodies. We have recently reviewed the literature data and collected 65 patients with acquired hemophilia A treated with this agent. In the majority of the cases, the dosing regimen of rituximab was 375 mg/m²/weekly for 4 weeks, with the cycle repeated if the patient relapsed. Although a response was observed in more than 90% of cases, we advise caution in the over-interpretation of these data as they are derived from case reports or small trials. Furthermore, most patients received concomitant immunosuppressive therapy, thus making the evaluation of the real effectiveness of this agent very difficult. For these reasons, in the absence of large prospective studies assessing the safety and efficacy of rituximab in acquired hemophilia, we prefer to use this agent, in association with steroids, as a second-line treatment.

Conclusions

Acquired hemophilia A is a rare disease associated with severe bleeding complications. Therefore, its prompt recognition is mandatory in order to initiate an early treatment. In the last few years, two agents (i.e., rFVIIa and rituximab) have significantly improved the therapeutic armamentarium for the management of this acquired hemorrhagic disorder. Indeed, while rFVIIa has proven to be an effective and safe tool for the treatment of acute bleeding related to FVIII autoantibodies, rituximab is a promising alternative option for the eradication of the autoantibody and restoration of normal hemostasis.
