Abstract

Hemochromatosis is a common genetic disorder in which iron may progressively accumulate in the liver, heart and other organs. The primary goal of therapy is iron depletion to normalize body iron stores and to prevent or decrease organ dysfunction. The primary therapy to normalize iron stores is phlebotomy. In this opinion paper, we discuss the indications for and monitoring of phlebotomy therapy to achieve iron depletion, maintenance therapy, dietary and pharmacological maneuvers that could reduce iron absorption, and the role of voluntary blood donation.
Introduction

Hemochromatosis is a common heritable disorder characterized by the progressive accumulation of iron due to increased absorption from dietary sources. The most common hemochromatosis genotype is homozygosity for HFE C282Y, although the role of HFE protein in the pathogenesis of the iron overload has not been clearly elucidated. Other mediators that affect iron absorption, transport, and mobilization include hepcidin, bone morphogenic protein 6, hemojuvelin, transferrin receptor-1 and -2, and ferroportin. The use of phlebotomy therapy to reduce body iron stores followed the clinical description of hemochromatosis by at least 50 years. Phlebotomy stimulates erythropoiesis and mobilizes iron from parenchymal cells and other storage sites.

In this opinion paper, we focus on the treatment of typical HFE C282Y homozygotes with iron overload. Many of these management concepts are also applicable to the treatment of patients with other types of iron overload, although the severity of iron overload and response to phlebotomy vary depending on the genetic subtype of hemochromatosis or other iron overload disorder. Further, the success of phlebotomy therapy depends on normal erythropoiesis. The diagnosis of iron overload is beyond the scope of this article. More patients have hyperferritinemia that is due to inflammatory conditions and liver diseases than to iron overload, and the risk for adverse events caused by inappropriate phlebotomy therapy in such patients may be great. Phlebotomy treatment of other conditions such as hepatitis C, fatty liver disease, and porphyria cutanea tarda is beyond the scope of this article.
Rationale for iron depletion therapy

It had been previously considered that most hemochromatosis patients have progressive iron accumulation. Excess iron is toxic to cells, an effect mediated through the production of free radicals and the Fenton reaction, although many in vitro iron toxicity studies used supra-physiological concentrations of iron. The previous rationale for phlebotomy therapy for all patients with hemochromatosis was that iron depletion would reduce or eliminate the potential for iron-mediated tissue injury. Iron toxicity has been difficult to demonstrate in animal models. An extrapolation unfounded by clinical studies was that iron depletion would improve the quantity and quality of life of all hemochromatosis patients, and that the benefits of therapy would outweigh any potential risks or adverse effects of phlebotomy therapy.

Do all C282Y homozygotes require phlebotomy therapy?

Since the development of diagnostic genetic testing for hemochromatosis, it has become apparent that approximately 50% of female and 20% of male adult C282Y homozygotes have normal serum ferritin (SF) levels and may never require phlebotomy therapy. The guidelines for the initiation of phlebotomy therapy published by expert groups before HFE mutation analysis was widely available recommended starting therapy in C282Y homozygotes with an elevated SF (>200 µg/L in women, >300 µg/L in men). This recommendation stems from the assumption that a person with hemochromatosis and an elevated SF level at presentation has already demonstrated accumulation of excess iron which would likely be progressive. Because most patients have been treated with phlebotomy after clinical or biochemical presentation, there has
been little opportunity to collect observations on the natural history of untreated hemochromatosis. Several large population-based studies have performed hemochromatosis genetic testing on participants many years into the study and used stored blood samples to measure SF over time in participants found to have C282Y homozygosity.\textsuperscript{10-15} These studies demonstrate that not all C282Y homozygotes, including those with an elevated SF level, are destined to have progressive iron overload.\textsuperscript{16,17} The degree of elevation of the SF level at presentation can be used to predict the risk of progression.\textsuperscript{13} An adult C282Y homozygote with a normal SF level at diagnosis is very unlikely to develop iron overload later.\textsuperscript{14} These observations from population screening studies may not be relevant to a C282Y homozygote with symptoms referred to initiate phlebotomy therapy. It is widely agreed that persons with hemochromatosis whose SF is $\geq 1000$ µg/L should undergo phlebotomy to achieve iron depletion.\textsuperscript{18} The decision to treat C282Y homozygotes with moderate elevations of SF (200 – 1000 µg/L) should consider patient preferences and clinical judgment (Table 1). The conventional approach is to treat all C282Y homozygotes with SF above the reference range. New information from population studies has demonstrated that SF levels do not rise progressively in all patients, and thus observation with follow-up SF measurements can be considered as an alternative management strategy. The presence of symptoms or elevated serum levels liver enzymes are not a prerequisite for initiating phlebotomy therapy.

**Clinical benefits of phlebotomy therapy**
A randomized study of phlebotomy therapy has not been done; therefore, it has been difficult to assess the clinical benefits of therapy. In a large survey of hemochromatosis patients in the U.S. and Canada, 76% of patients received phlebotomy in a hospital or physician’s office and 30% at a blood center. More than three-quarters of patients reported that their phlebotomy therapy was beneficial, whereas 15% expressed a negative opinion about therapy. The primary negative aspects were venous access problems, time (for travel, waiting, and the procedure), and the fact that in many cases the blood is not used for donation. Fifty-nine percent reported that if they could take a pill with a 5% chance of serious adverse effects, they would prefer that treatment to phlebotomy.19;20

Liver fibrosis, cirrhosis, and hepatocellular carcinoma are the most serious complications of iron overload. In population-based studies, these complications occur in ~5% of male and <1% of female C282Y homozygotes.21;22 The presence of symptoms related to iron overload in C282Y homozygotes found in a population screening study was 28.4% in men and 1.2% in women.21 Several studies that evaluated liver biopsies before and after phlebotomy therapy demonstrated that hepatic fibrosis can be reversed by phlebotomy therapy.23;24 Hepatic elastography is a non-invasive tool that may be useful to monitor this potential benefit without the need for liver biopsy.25 Liver biopsy has moved from a diagnostic test to a prognostic test in many patients with hemochromatosis. It should be considered in C282Y homozygotes with SF ≥1000 µg/L, and in patients with non-iron risk factors for liver disease (e.g., alcohol, obesity, viral hepatitis). Liver iron concentration was most useful when the iron
concentration / age (hepatic iron index) was used as a diagnostic test for hemochromatosis. This index is rarely useful in the current era of genetic testing.

Severe myocardial siderosis does not develop in most persons with \textit{HFE} hemochromatosis. Forty-three C282Y homozygotes with iron overload and New York Heart Association functional class I had increased strain rate, a sensitive indicator of left ventricular diastolic function. Strain rate was significantly correlated with biomarkers of oxidative stress, but not with serum iron measures. These abnormalities were not observed in control subjects who lacked \textit{HFE} C282Y and H63D.\textsuperscript{26} Cardiac dysfunction due to myocardial siderosis is typically more severe in persons with hemochromatosis due to \textit{HJV} or \textit{TFR2} mutations than in persons with \textit{HFE} hemochromatosis, and may manifest as dyspnea, orthopnea, or arrhythmia that often improves after iron depletion.\textsuperscript{26}

Diabetes mellitus, infrequently due to iron overload alone, is often unchanged by phlebotomy therapy, although some patients report improvement in blood glucose management.\textsuperscript{27} Skin hyperpigmentation often decreases after phlebotomy. Many patients who report pre-treatment fatigue indicate that this symptom improves with phlebotomy. Some patients report being energized by phlebotomy; some are reluctant to discontinue phlebotomy treatment after iron depletion is achieved.

A distinctive form of arthropathy occurs in some patients with hemochromatosis, especially women;\textsuperscript{28} many other patients have age-related or other types of arthritis.
similar to those observed in persons without hemochromatosis. Consistent with previous reports, our informal observations suggest that arthralgias increase during phlebotomy therapy in some patients; some report decreased joint pain or swelling after iron depletion is achieved. Arthropathy in many cases appears to be unaffected by phlebotomy management. There are no data from prospective studies that would predict the effect of therapeutic phlebotomy on future arthritis outcomes.

**Does phlebotomy treatment improve survival?**

Studies from tertiary referral centers have documented that survival is significantly less in hemochromatosis patients with cirrhosis than in those without cirrhosis. Diabetes mellitus can also adversely influence survival in hemochromatosis patients, but most diabetic patients with hemochromatosis also have cirrhosis. The major goal of early diagnosis and iron depletion therapy is to prevent cirrhosis. Hepatocellular carcinoma occurs predominantly in hemochromatosis patients who have cirrhosis, and therefore prevention of cirrhosis would likely also reduce the risk of hepatocellular carcinoma. Patients with cirrhosis should undergo surveillance for hepatocellular carcinoma with abdominal ultrasonography every six months. Because an increase in the prevalence of colon and breast cancer has been described in C282Y homozygotes, patients should be encouraged to undergo colon and breast cancer screening as recommended for the general population.

Survival benefits of iron depletion, if any, have been difficult to demonstrate, because a small minority of persons with hemochromatosis have or will ever develop cirrhosis.
Unphlebotomized patients with hemochromatosis have a normal lifespan when the selection criterion is based on either HFE genotype or biochemical phenotype identified in population screening. There are no data that show definitively that phlebotomy improves survival in such subjects, and such data are unlikely to be obtained due to ethical issues.33 Large population-based studies of cardiac disease have not demonstrated a reduced survival in untreated hemochromatosis patients over follow-up intervals of 17 – 30 years.10;12 Patients discovered to have hemochromatosis in medical care because they have symptoms or biochemical manifestations attributable to iron overload may have greater risk to develop cirrhosis than those discovered in screening programs, but it is unlikely that a randomized clinical trial of phlebotomy therapy in such patients would be acceptable. Thus, observations gleaned largely from population studies in which C282Y homozygotes were identified long after initiation of the study do not imply that a referred symptomatic patient should not be offered phlebotomy therapy. For such patients, there is evidence that liver and cardiac function improve after iron depletion.24;34

Performing phlebotomy therapy

Patients undergo therapeutic phlebotomy in an ambulatory care facility while reclining or sitting; treatments are performed by nurses. One of us utilizes skilled nurses to oversee phlebotomy therapy; the other performs this management personally. One of us employs a 16-gauge straight needle and collection bag (Blood Pack MR6102®, Baxter, Deerfield, IL); the other uses a 19-gauge butterfly needle connected to an evacuated bottle via an extension set (Baxter 1A8503® and 1C8624®, respectively). Blood
(typically 500 mL) is removed over 15 - 30 minutes. The size of the needle and the venipuncture site can be adjusted by an experienced phlebotomist, as appropriate. A hemoglobin concentration is measured at the time of each treatment. If the value is <11 g/dL, the treatment schedule is modified to 500 mL every other week; lower volumes (250-400 mL per session) are optimal for some persons of small body habitus or those whose hemoglobin levels are restored slowly after phlebotomy. Pre-treatment hydration and the concomitant administration of a salt-containing sport beverage (e.g., Gatorade®) is a simple method of maintaining plasma volume during and after phlebotomy treatments.

**Monitoring iron measures during phlebotomy therapy**

Management of iron overload is based on measurements of SF because these measures are directly related to the amount of stored iron. Accordingly, we quantify SF every month (or after every four phlebotomy sessions) in patients with hyperferritinemia undergoing therapy to induce iron depletion. After SF levels are <200 µg/L, we measure SF every 1-2 weeks (or after every one-two phlebotomy sessions).

Transferrin saturation is elevated in most patients with hemochromatosis who have hyperferritinemia due to iron overload, although day-to-day values fluctuate in the same person. Plasma iron species unassociated with ferritin or transferrin occur in some persons with hemochromatosis, typically when transferrin saturation is elevated. These include non-transferrin-bound iron (NTBI) and labile plasma iron (LPI). Both may promote tissue overload and consequent damage.\textsuperscript{35-39} NTBI and LPI are mainly found when transferrin saturation exceeds 45% and 75%, respectively,\textsuperscript{39} although NTBI
persists in some subjects with low serum iron level and high serum iron-binding capacity.\textsuperscript{40} Thus, measurement of transferrin saturation during phlebotomy to achieve iron depletion would provide surrogate qualitative assessments of NTBI and LPI. Regardless, no bioclinical correlate of either NTBI or LPI has been reported in \textit{HFE} C282Y homozygotes, nor is there evidence-based management to reduce NTBI and LPI other than iron depletion.

\textbf{Endpoints of phlebotomy therapy}

There are different ways to follow the progress of phlebotomy therapy. At our centers, patients are treated until the SF is \textasciitilde{}50 µg/L, a value in the lower reference range that signifies that there is little or no storage iron. Lynch and colleagues measured iron absorption from test meals in hemochromatosis patients who were untreated (SF >1000 µg/L), partially treated with phlebotomy (mean SF 538 µg/L; range 210-786 µg/L), and “fully” treated by phlebotomy (mean SF 14 µg/L; range 10-21 µg/L).\textsuperscript{41} Non-heme iron absorption was 9\%, 12\%, and 42\% in these respective groups, whereas heme iron absorption was 41\%, 50\%, and 39\%. These results demonstrate that non-heme iron absorption is markedly increased by phlebotomy that results in SF \textasciitilde{}20 µg/L, and could lead to unnecessary induction and maintenance phlebotomy. The absorption of heme iron is relatively high but stable, regardless of the magnitude of iron stores. Accordingly, the SF \textasciitilde{}50 µg/L criterion enhances absorption of non-heme iron less than would occur at SF \textasciitilde{}20 µg/L, and allows some “room” for iron re-accumulation into the mid- or upper reference range. The decrease in SF levels with phlebotomy is infrequently linear; the rate of iron mobilization may be higher in patients with cirrhosis.\textsuperscript{42} There are significant
positive correlations between the amount of blood removed by phlebotomy to reach iron depletion and either the initial SF level, hepatic iron concentration measured in liver biopsy specimens, or liver iron levels estimated by MRI configured to measure liver iron.\textsuperscript{43,44}

Measuring SF is the preferred means to monitor the progress of therapeutic phlebotomy to induce iron depletion. We discontinue phlebotomy therapy in most patients when their SF level is in the lower reference range (~50 µg/L) (Figure 1). Some patient support groups have advocated more intensive phlebotomy therapy to achieve and maintain much lower SF levels, but some patients so treated develop fatigue and other symptoms as they develop iron deficiency. Transferrin saturation, often elevated in hemochromatosis, usually falls much less rapidly in response to phlebotomy therapy than the SF level. Transferrin saturation may remain elevated when body iron stores and SF values are subnormal; phlebotomy that reduces transferrin saturation to low normal values may result in iron deficiency.\textsuperscript{45} Thus, we recommend that SF, not transferrin saturation, be used as the indicator for cessation of phlebotomy therapy. An alternative approach is to defer weekly phlebotomy in subjects without chronic anemia if hemoglobin is <12 g/dL, and to discontinue weekly phlebotomy to induce iron depletion if hemoglobin is <11 g/dL for more than three consecutive weeks (Figure 1).\textsuperscript{9,46,47} Another approach is to discontinue phlebotomy to induce iron depletion when MCV is ≥3% below pre-treatment baseline.\textsuperscript{48} Patients are usually more insistent on maintaining low SF levels than physicians. There is little clinical evidence to suggest that a hemochromatosis patient with a SF level in the middle or high reference range suffers
subacute iron toxicity or organ dysfunction. The value of maintenance phlebotomy therapy to keep iron stores within the reference range has not been clearly established. We advise patients who had symptoms or signs reasonably attributable to iron overload at diagnosis that were alleviated by iron depletion and those with SF $\geq 1000$ μg/L at diagnosis to maintain low iron stores with periodic phlebotomy. Reports of achieving and maintaining low iron stores in hemochromatosis patients who also have common liver disorders such as non-alcoholic steatosis or hepatitis C reveal inconsistent results.\textsuperscript{49,50}

Iron accumulation rates vary greatly amongst C282Y homozygotes; this variability persists after iron depletion. Women are less likely than men to re-accumulate iron rapidly. Some patients with hemochromatosis monitored as long as 11 years after initial iron depletion and not treated with maintenance therapy did not re-accumulate iron.\textsuperscript{51} We advise measuring SF six months after cessation of therapy to estimate the risk of iron re-accumulation and to personalize maintenance therapy based on these observations.

**Intolerance of phlebotomy**

Decreasing the phlebotomy interval to every two weeks is necessary in some patients, especially women.\textsuperscript{9} In patients who report hypotension or dizziness, the volume of oral salt drinks can be increased; rarely, an intravenous saline solution must be infused to restore blood volume after phlebotomy. The volume of blood removed can be decreased, but this prolongs the overall duration of therapy to achieve iron depletion.
Phlebitis can be treated by warm compresses, non-steroidal anti-inflammatory drugs, and rotating venipuncture sites. The use of indwelling catheters entails greater risks.

Inadequate venous access usually requires a change in the management plan. No phlebotomy therapy may be acceptable for an intolerant patient with SF <1000 µg/L with no organ dysfunction. The development of anemia after few phlebotomies may indicate that the SF elevation was not due to iron overload. The evidence for iron overload (liver biopsy, MRI, etc.) should be reviewed before further phlebotomy is performed.

Anecdotal reports suggest that hypotestosteronemia, erythropoietin deficiency, or the commitment of time required to undergo phlebotomy therapy may account for anemia or fatigue in some cases.⁵²⁻⁵³

**Erythrocytapheresis**

Therapeutic erythrocytapheresis (TE), like therapeutic phlebotomy, removes iron predominantly as hemoglobin (Table 1). Like patients treated with phlebotomy, those managed with TE must have no or mild anemia, and a rate of effective erythropoiesis that is sufficient to replace erythrocyte losses rapidly. Isovolemic, large-volume erythrocytapheresis removes more blood erythrocytes per session than phlebotomy, while sparing plasma proteins, coagulation factors, and platelets. In small case series, erythrocytapheresis reduced iron measures in hemochromatosis patients with severe iron overload, intolerance of phlebotomy, or co-inheritance of β-thalassemia.⁵⁴ Erythropoietin administration may facilitate such treatment in some cases.⁵⁵
Performing TE requires the apheresis apparatus itself, a skilled technician, careful patient selection, and venipuncture with large-bore needles to accommodate the flow and pressure requirements of apheresis machines. Patients with hemochromatosis treated with erythrocytapheresis to achieve iron depletion should have pre-procedure hemoglobin ≥12 g/dL. The volume of erythrocytes removed at each treatment should be adjusted based on consideration of gender, height, weight, and pre-treatment hematocrit, such that the minimal post-procedure hematocrit is 30%; patients with post-procedure hypovolemia benefit from infusion of normal saline. Additional procedures are performed every two weeks in persons whose hemoglobin level has returned to ≥12 g/dL; an interval of three weeks between procedures is required in some patients, especially women. SF is monitored in the same manner as previously described for therapeutic phlebotomy.54;56;57

TE achieves iron depletion in persons with hemochromatosis in a shorter treatment period than therapeutic phlebotomy.56 In a pilot study of six hemochromatosis patients treated with TE, the total number and the duration of treatments in the TE group was ~70% lower than that in historical control subjects managed with therapeutic phlebotomy. Although the costs of a single TE session were higher, the total costs to induce iron depletion were similar to or lower than those with therapeutic phlebotomy.56 TE appears to be safe and rapid, and may achieve iron depletion in patients with severe iron overload more rapidly than phlebotomy therapy. Regardless, the availability of and clinical experience with TE for management of iron overload due to hemochromatosis
are limited. The present authors have not treated patients with hemochromatosis using TE.

Medications

Iron chelation drugs. Deferoxamine (DFO), a parenterally administered iron chelator, induced iron depletion in patients with hemochromatosis who were unable to undergo phlebotomy therapy. In short-term studies, DFO treatment was as effective as phlebotomy of 500 mL weekly in removing iron from the liver. Much experience with the poor compliance and acceptability of DFO therapy in patients with non-hemochromatosis iron overload suggests that DFO treatment would not be generally satisfactory for persons with hemochromatosis (Table 1).

Deferasirox (DFX), an oral iron chelator, was administered daily for 24 weeks to hemochromatosis patients with \textit{HFE} C282Y homozygosity, pre-treatment SF 300–2,000 µg/L, transferrin saturation >45%, and no history of cirrhosis in a phase I/II study (Table 1); one of us was an investigator in this clinical trial. The primary endpoint was the incidence and severity of adverse events; secondary endpoints were change in SF, time to SF normalization (<100 µg/L), longitudinal course of SF, and pharmacokinetics of DFX. Adverse events, documented in <10% of patients, included diarrhea, nausea, abdominal pain, and elevated serum ALT or creatinine levels. These events were dose-related and resolved with dose reduction or cessation of DFX therapy; 77% of patients who were treated initially completed the study. Time course of the decline in SF was
dose-dependent. Only the 5 and 10 mg/kg/d doses are being considered for further study in \textit{HFE} hemochromatosis, largely due to the rate of adverse events at higher doses.\textsuperscript{59}

There are no reports of the treatment of \textit{HFE} hemochromatosis with the oral iron chelator deferiprone (DFP). The combination of DFO and DFP have been used to treat severe iron overload complicated by cardiomyopathy in a patient with a juvenile hemochromatosis phenotype.\textsuperscript{60} DFP is not licensed in the U.S.

Phase III trials comparing phlebotomy with oral chelation therapy should be conducted, but may need to await a means to detect which C282Y homozygotes will develop progressive, injurious iron overload and therefore potentially benefit from treatment. Clinical trials must be designed to determine if oral chelation therapy can eliminate hepatic iron deposits without causing additional liver injury, and if hepatic fibrosis and cirrhosis caused by iron overload can be reversed.\textsuperscript{61} Treatment schedules for maintaining low body iron stores after iron depletion has been achieved must also be established.\textsuperscript{61}

\textit{Proton pump inhibitors (PPIs).} PPIs inhibited the absorption of non-heme iron from a test meal and the habitual diet in hemochromatosis patients with \textit{HFE C282Y} homozygosity diagnosed in medical care.\textsuperscript{62} Achlorhydria or drugs that decrease gastric acid secretion diminish absorption of inorganic iron by reducing its solubility. In addition, iron uptake into enterocytes mediated by intestinal divalent metal transporter-1 requires
proton co-transport; the protons are presumably derived from gastric acid that enters the duodenum. These observations suggest that chronic use of PPIs by C282Y homozygotes could either diminish the severity of iron overload that would otherwise occur due to excess absorption of inorganic iron from dietary sources, or reduce requirements for maintenance phlebotomy. Regardless, there are insufficient data to recommend the routine administration of proton-pump inhibitors to patients with hemochromatosis for the purpose of decreasing iron absorption. Histamine receptor-2 antagonists reduced dietary iron absorption in short-term studies of persons without hemochromatosis, but continuous use of cimetidine for three years did not alter hemoglobin or plasma iron levels significantly. The greater influence of PPIs than histamine receptor-2 antagonists on SF levels could be explained by the direct inhibition of gastric acid secretion and longer duration of action characteristic of PPIs.

**Dietary management**

Evidence-based dietary advice for patients with hemochromatosis could diminish the rate of increase in iron stores, and decrease the expressivity of iron overload due to hemochromatosis in populations. The rate of compliance with recommended changes in diet in Australian *HFE* C282Y homozygotes detected in workplace screening was high. Our dietary management recommendations are displayed in Table 2.

*Iron.* Absorption of heme and non-heme iron from unfortified test meals is far greater in hemochromatosis patients diagnosed in medical care than would be predicted from the relationship between iron absorption and SF levels observed in normal volunteers.
Further, there is a significant inverse relationship of absorption of non-heme iron with increasing SF levels. In contrast, heme iron absorption was not significantly related to SF levels. In women in the U.K., HFE C282Y homozygotes had SF concentrations 2.4 times higher than women with wild-type HFE genotypes. The association of heme iron intake with SF levels estimated using food frequency questionnaires (from meat, fish, and poultry) was 2.0 times greater (range 1.2-3.2) in C282Y homozygotes than subjects with other HFE genotypes; estimated non-heme iron intake had little effect on SF levels. In women in the Netherlands aged >50 years, C282Y homozygotes (and C282Y/H63D compound heterozygotes) had significantly higher SF concentrations than women with other HFE genotypes. C282Y homozygotes and C282Y/H63D compound heterozygotes who consumed relatively high amounts of heme iron had the highest SF concentrations. It has been proposed that the high rate of expression of iron overload and associated manifestations in hemochromatosis homozygotes in Australia is due to the high national rate of meat consumption. Red meat consumption was positively associated with higher SF levels in adults in Busselton, Australia, regardless of HFE genotype. Altogether, some persons with hemochromatosis may be especially susceptible to iron loading from diets in which a high proportion of available iron is present as heme, although they may also absorb increased fractions of non-heme iron.

Fortification of food with inorganic iron may increase the severity of iron overload in persons with hemochromatosis. In seven treated hemochromatosis patients (SF <33 µg/L), the absorption of non-heme iron from a test meal was measured using the extrinsic tag technique to simulate the effects of fortification. Doubling of the iron dose
produced a 43% increase in mean absorbed iron from 1.6 mg to 2.2 mg, a proportional increase similar to that in normal subjects.\textsuperscript{76} In Sweden, fortification before 1995 accounted for 42% of the mean daily dietary iron content, although Swedish hemochromatosis homozygotes had lower iron burdens, on average, than those in Australia.\textsuperscript{77} Decreased fortification in Sweden since 1995 is expected to decrease the rate of iron accumulation in persons with hemochromatosis.\textsuperscript{77} It is likewise predicted that iron fortification of wheat flour at the current U.S. levels would accelerate the initial rate of iron loading in persons with hemochromatosis from 1.7 to 2.1 g; if the same calculations were based on untreated hemochromatosis patients with SF $\geq$1000 µg/L, the predicted difference in absorption between unfortified and fortified diets falls to $\sim$100 mg annually. These estimates agree with earlier predictions that the greatest impact of iron fortification is at the early stages of the condition, and that the accelerated evolution of clinical disease is directly proportional to the amount of fortification iron added.\textsuperscript{75,78} If dietary iron intake were increased by 20% with fortification, the predicted time required to develop clinical manifestations is likewise shortened by 20%. Another predicted influence of iron fortification is its effect on the frequency of maintenance phlebotomies required to maintain low iron reserves in fully treated patients. With a typical phlebotomy rate of 4-6 times annually, a 20% increase in dietary iron by fortification of wheat flour would necessitate 1-2 additional bleedings per year.\textsuperscript{77,79}

Some \textit{HFE} C282Y homozygotes absorb supplemental non-heme iron readily. The hemoglobin levels of C282Y homozygotes with iron-deficiency anemia who took ferrous sulfate daily (325 mg) returned to normal within 2-6 weeks.\textsuperscript{45} A man who took daily
ferrous sulfate for beta-thalassemia minor (153 g Fe over 7 years) was subsequently diagnosed to have hemochromatosis, C282Y homozygosity, and diabetes mellitus; 32 g of iron was removed by phlebotomy to achieve iron depletion.\textsuperscript{80} Urinary hepcidin levels did not increase in C282Y homozygotes given a single 65 mg iron dose as ferrous sulfate, regardless of their state of iron depletion by therapeutic phlebotomy.\textsuperscript{81} Although 27 percent of persons diagnosed to have hemochromatosis reported that they had previously taken supplements that contained iron,\textsuperscript{19} the effect of supplemental iron taken before diagnosis of hemochromatosis on the expression of iron overload in large populations of C282Y homozygotes is unknown.

\textit{Non-iron diet items.} Alcohol loading down-regulates hepatic hepcidin expression and increases iron absorption in humans and mice without hemochromatosis.\textsuperscript{82,83} Mice of alcohol-susceptible strains that were also homozygous for a knockout of \textit{Hfe} (orthologue of human \textit{HFE} gene) had reduced iron absorption and serum hepcidin levels in response to alcohol treatment.\textsuperscript{84} This indicates that either maximal suppression of hepcidin levels had already occurred as a result of the \textit{Hfe} knockout, or that Hfe protein was a component of the pathway utilized by ethanol in suppressing hepcidin production and increasing iron absorption.\textsuperscript{84} Direct measures of stored iron were similar in two groups of persons with hemochromatosis: those who consumed >100 g of alcohol daily and nondrinkers or moderate drinkers who consumed <100 g of alcohol daily; complications of alcoholism were common in the first group.\textsuperscript{85} If dietary iron intake differs between persons with hemochromatosis who are or are not heavy drinkers, such differences would appear to have little effect on iron phenotypes. Altogether, it appears
that the most likely reason why heavy alcohol consumption accentuates the expression of hemochromatosis is the additive co-factor effect of iron and alcohol, both of which cause oxidative stress, hepatic stellate cell activation, and hepatic fibrogenesis.\textsuperscript{84}

Black tea inhibits the absorption of non-heme iron, presumably due to the intraluminal binding of iron by tannate. In 18 German patients with hemochromatosis, iron absorption was significantly lower when a test meal was accompanied by drinks of tea instead of water. After iron depletion was achieved by phlebotomy in the same patients, regular tea drinking with meals reduced the frequency of maintenance phlebotomies required during an interval of one year.\textsuperscript{86} In Australian subjects, reports of tea consumption on a food questionnaire were not significantly associated with SF concentrations, regardless of \textit{HFE} genotype.\textsuperscript{73}

Reports of higher levels of non-citrus fresh fruit intake were associated with significantly lower SF levels in men in Busselton, Australia, irrespective of \textit{HFE} genotype. Mean SF levels were lower by 20\% in men who consumed two or more pieces of fruit per day, on average, than in those whose average consumption was less than one piece of fruit daily. This effect was not observed in women. Consumption of citrus fruits and citrus juices had no significant effects in either sex.\textsuperscript{73} We advise patients to limit their intakes of supplemental vitamin C to 500 mg daily.\textsuperscript{9}

Some patients with hemochromatosis with or without cirrhosis have developed infection with \textit{Vibrio vulnificus}, a free-living Gram-negative bacillus that grows as normal marine
flora and is distributed world-wide in warm, coastal waters.\textsuperscript{87} In the U.S., most infections have occurred in regions adjacent to the Gulf of Mexico; some infections are fatal. Abundance of iron in blood and tissues and decreased plasma hepcidin in hemochromatosis may increase risk for infection. In persons with hemochromatosis, \textit{V. vulnificus} has been reported to cause primary septicemia due to ingestion of uncooked oysters or other raw shellfish (or of cooked food contaminated with seawater drippings); and wound infections due to contact of superficial wounds with seawater that contains \textit{V. vulnificus}. Thus, physicians who treat patients with hemochromatosis or iron overload should educate their patients about \textit{V. vulnificus} infections. Like expert hemochromatosis management groups, we recommend that patients diagnosed to have hemochromatosis or iron overload not consume raw shellfish, regardless of iron overload status.\textsuperscript{52} It is also prudent that persons diagnosed to have hemochromatosis or iron overload prevent contact of wounds with seawater, and avoid direct handling of uncooked saltwater finfish or shellfish.\textsuperscript{87} Thoroughly cooked seafood uncontaminated with seawater drippings does not contain viable \textit{V. vulnificus}, and is thus safe for consumption.

**Hemochromatosis patients as voluntary blood donors**

Many persons with hemochromatosis donate blood or qualify as blood donors,\textsuperscript{88-90} and blood removed for therapeutic phlebotomy can be used as a means of augmenting the blood supply for transfusion.\textsuperscript{91,92} In August 2001, the U.S. Food and Drug Administration (in a publication that included the U.S. Department of Health and Human Services and the Center for Biologics Evaluation and Research) issued a policy of variances for
collecting blood from hemochromatosis donors that accomplished at least four major aims: 1) the policy allowed the transfusion of blood from individuals with hemochromatosis if the blood met all known safety standards; 2) the policy eliminated financial incentives for hemochromatosis patients to falsify responses to blood bank questions about health status and about possible behaviors that increased the risk of transmissible infections; 3) blood banks that accepted the blood for transfusion from any hemochromatosis patient were required to provide phlebotomy therapy without charge to all hemochromatosis patients who came to the blood bank; and 4) the policy authorized a blood bank to perform phlebotomy therapy according to the prescribing physician’s written orders about frequency and hematocrit/hemoglobin limits (Title 21, Code of Federal Regulations, Section 640.120 (21 CFR 640.120)).

In practice, some U.S. blood banks obtained the variances, are involved in therapy of patients with hemochromatosis, and report informally that such patients supplement their blood supplies. Most patients treated at blood banks must undergo SF and other evaluations at the offices of their physicians. We have also encountered patients who donated blood for transfusion without revealing their diagnosis of hemochromatosis and without obtaining SF measurements from their physicians, presumably due to financial considerations. Some have had symptomatic iron deficiency with anemia; others had uncontrolled iron overload. Many U.S. blood banks have declined to obtain the variances and prefer to obtain blood units solely from volunteer donors.
It has been postulated that the use of hemochromatosis blood could augment the national blood supply. Two ethical issues germane to this postulate are that no person with hemochromatosis has the right to insist that his/her blood be used for transfusion, and that hemochromatosis patients are not obligated to donate therapeutic phlebotomy blood for transfusion.\textsuperscript{93} The results of a study at the National Institutes of Health demonstrated that recruitment of healthy hemochromatosis donors augmented the intramural blood supply significantly.\textsuperscript{91} In a questionnaire survey of donors from eight U.S. blood centers, 0.8\% of the 52,650 responding donors reported that they had hemochromatosis.\textsuperscript{94} In 16 blood centers that did not recruit hemochromatosis patients, only 0.4\% of 1.67 million units of red blood cells were donated by hemochromatosis patients.\textsuperscript{95} Both of us refer patients with hemochromatosis to blood centers for therapeutic phlebotomy, as appropriate.

In Canada, blood from hemochromatosis patients whose blood meets other safety criteria has been used for transfusion since 1991.\textsuperscript{89} In Wales and Sweden, hemochromatosis patients whose blood meets safety standards is used for transfusion. Because these individuals had iron overload, they are allowed to donate blood more frequently than other volunteer donors.\textsuperscript{96,97} In France, members of a working group recommended continuation of the policy not to allow blood donation by hemochromatosis patients who had an elevated SF concentration or evidence of iron-associated organ injury or illness.\textsuperscript{98} In 2000, investigators in New Zealand recommended that a national blood banking policy be developed to allow transfusion of
the blood that is donated by healthy hemochromatosis patients if the blood meets all safety standards.99

Summary

For most hemochromatosis patients, standard therapy is the weekly removal of blood to bring the SF level into the low reference range. The major medical benefit of this therapy is the prevention or reversal of liver fibrosis; some patients report decreased dyspnea, pigmentation, fatigue, or arthralgia, or improved control of diabetes mellitus. The natural history of untreated hemochromatosis has demonstrated that some patients do not have progressive iron overload. Iron chelation therapy is rarely ideal for hemochromatosis patients due to cost, potential toxicity, and relative lack of documentation of benefits. Dietary restrictions and medications to reduce iron absorption seem rational, but have not been evaluated in prospective randomized clinical trials. Future studies that would enable us to predict the progression of iron overload in an individual C282Y homozygote could lead to personalized therapeutic approaches.

<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Erythrocytapheresis</td>
<td>venipuncture</td>
<td>rapid, safe; may be preferred for patients with severe iron overload</td>
<td>blood as hemoglobin (1 mL erythrocytes = 1 mg Fe)</td>
<td>excellent in selected patients</td>
<td>limited clinical experience; requires special apparatus and facility, limited availability; expensive</td>
<td>transient hypovolemia; fatigue; increases iron absorption; citrate reaction; iron deficiency if monitoring inadequate or inappropriate</td>
</tr>
<tr>
<td>Deferoxamine (DFO) chelation</td>
<td>subcutaneous infusion</td>
<td>much clinical experience in iron overload patients without hemochromatosis; widely available; consider using in patients intolerant of phlebotomy</td>
<td>urine as chelate; daily iron excretion variable</td>
<td>fair</td>
<td>few reports of use in hemochromatosis, mostly to achieve iron depletion; inadequate chelation of cardiac iron in some cases; expensive</td>
<td>infusion site reactions; hearing, vision, growth, skeletal abnormalities; zinc deficiency; Yersinia infection</td>
</tr>
<tr>
<td>Deferasirox (DFX) chelation</td>
<td>oral</td>
<td>good chelation of hepatic iron; consider using in patients with inadequate venous access or intolerant of phlebotomy</td>
<td>stool as chelate; daily iron excretion variable</td>
<td>fair</td>
<td>few reports of use in hemochromatosis to achieve iron depletion; no clear benefit for patients with iron-induced cardiomyopathy; expensive</td>
<td>toxicity often dose-dependent; gastrointestinal symptoms; transaminase elevations; elevation of serum creatinine;</td>
</tr>
</tbody>
</table>
It is not feasible to estimate net iron loss or gain attributable to diet or medications in individual patients using routine clinical techniques. Some patients with juvenile-onset hemochromatosis, severe iron overload, and iron-induced cardiomyopathy may benefit from combined treatment with phlebotomy and DFO or DFX.
Table 2. Dietary management recommendations for persons with hemochromatosis

<table>
<thead>
<tr>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Avoid supplemental iron</td>
</tr>
<tr>
<td>Consume red meats in moderation</td>
</tr>
<tr>
<td>Consume ethanol in moderation(^1)</td>
</tr>
<tr>
<td>Limit supplemental vitamin C to 500 mg daily</td>
</tr>
<tr>
<td>Use mineral supplements for specific deficiencies only(^2)</td>
</tr>
<tr>
<td>Do not consume raw shellfish</td>
</tr>
<tr>
<td>Do not consume cooked seafood contaminated with seawater drippings</td>
</tr>
<tr>
<td>Avoid contact of seawater with cuts or other open skin lesions</td>
</tr>
</tbody>
</table>

\(^1\)This recommendation applies to persons without liver abnormalities. Persons with evidence of liver injury such as elevated serum concentrations of hepatic enzymes or hepatomegaly should consume little or no ethanol. Persons with cirrhosis should abstain from consuming ethanol.
Legend to Figures

Figure 1. A clinical guide to phlebotomy management of *HFE* C282Y homozygotes.

(TS = transferrin saturation; SF = serum ferritin; IO = iron overload).
C282Y homozygote

- TS normal
  - SF normal
    - Observe
      - May never develop IO

- TS elevated
  - SF elevated
    - Hemoglobin <11 g/dL for 3 weeks
      - Discontinue phlebotomy
    - Hemoglobin <12 g/dL
      - Phlebotomy every 2 weeks
        - SF monthly until <200 µg/L, then every 1-2 weeks until SF ~50 µg/L

- TS elevated
  - SF normal
    - Observe
      - May develop elevated SF and IO

- Hemoglobin >12 g/dL
  - Weekly phlebotomy
